Neurotensin is a tridecapeptide (pGlu–Leu–Tyr–Glu–Asn–Lys–Pro–Arg–Arg–Pro–Tyr–Ile–Leu–COOH)[1] isolated from bovine hypothalami[2]. Using a sensitive and specific radioimmunoassay, Carraway and Leeman have demonstrated immunoreactive neurotensin in hypothalamic extracts of rat, mouse, rabbit and human tissue[3]. Intravenous (i.v.) administration of neurotensin to rats has been reported to cause hypotension (minimum effective dose 100 pmol kg^{-1} = 0.167 μg kg^{-1}), cyanosis (minimum effective dose 1 nmol kg^{-1} = 1.67 μg kg^{-1})[2], and hyperglycaemia (minimum effective dose 200 pmol kg^{-1} = 0.33 μg kg^{-1})[4]. These effects are not prevented by adrenalectomy or hypophysectomy. The hypotensive effects are not altered by α- or β-adrenergic blockers. Neurotensin also stimulates the contraction of guinea pig ileum while relaxing rat duodenum *in vitro*. Neurotensin is as potent as bradykinin in its effects on guinea pig ileum and rat duodenum and thus is classified as a kinin[2]. It increases plasma gonadotropin levels in ovariectomised, oestrogen–progesterone-treated rats after intravenous injection (minimum effective dose 5 nmol kg^{-1} = 8.4 μg kg^{-1})[5]. Intravenous administration of a dose of 3 μg kg^{-1} to rats produces hypoinsulinaemia, hyperglycaemia and hyperglucagonaemia[6].

Intracisternally (i.c.) administered thyrotropin-releasing hormone (TRH, effective dose 10 μg) and TRH analogues antagonise the depressant and hypothermic properties of various barbiturates[7–9] and ethanol[10]. Neurotensin, administered i.c. but not peripherally, potentiates markedly the sedative effects of pentobarbital in the mouse[11]. To understand this apparent synergistic interaction with pentobarbital further, we have

Fig. 1 Effect of i.c. neurotensin on the core temperature of mice subjected to a cold environment (4 °C). Data are expressed as °C±s.e.m. Experimental values were compared with those of controls by Student's *t*-test (two-tailed). investigated the effects of centrally administered neurotensin on thermoregulation.

Adult male Swiss–Webster mice (24–25 g) were anaesthetised lightly with ether and injected i.c. with neurotensin (0.03–30 μg in 10 μl of vehicle) or 10 μl of vehicle (0.9% NaCl solution). Recovery from anaesthesia required about 1 min. Mice were then placed in individual plastic cages without bedding in a room maintained at 4 °C or room temperature (25 °C). Rectal temperatures were assessed at 30-min intervals with a thermistor probe. TRH, luteinising hormone-releasing hormone (LHRH), melanocyte-stimulating hormone-release-inhibiting hormone (MIF I), substance P and somatotropin release-inhibiting hormone (SRIF) were also tested at 4 °C by intracisternal injection in doses equimolar to 30 μg of neurotensin. Neurotensin was also injected i.v. at 10, 30 and 100 μg kg^{-1}. Those doses were substantially greater than those reported to cause peripheral vascular changes and were administered to assess the possibility that such changes contribute to cold-induced hypothermia. Differences in rectal temperatures between control and experimental groups were analysed for statistical significance by Student's t-test (two-tailed).

*Doses equimolar to 30 μg of neurotensin in 10 μl of vehicle (0.9% NaCl).

Neurotensin given i.c. to mice in a cold environment markedly accentuated the decline in core temperature over 120 min (Fig. 1). This effect was dose related; the minimum dose showing an effect at 30 min was 0.03 μg. The i.c. administration of 10 and 30 μg of neurotensin also caused a significant decrease in core temperature at 25 °C (Table 1). The intracisternal delivery of TRH, LHRH, MIF, substance P and SRIF failed to produce any significant changes in rectal temperature from the control values at 4 °C during the 2-h period of observation (Table 2). In contrast to the action of neurotensin after intracisternal delivery no significant effect on cold tolerance was observed after intravenous administration of neurotensin (Table 3).

TRH is the only peptide previously reported to affect thermoregulation. Intracerebroventricular and intravenous administration of TRH has been reported to induce hyperthermia in rabbits[12], while others have shown that intracerebroventricular TRH induces hypothermia in cats[13]. Both the hypothermia at 25 °C and the considerable changes in cold tolerance at 4 °C observed after the i.c. administration of neurotensin suggest that it is involved in central thermoregulatory processes. This is also suggested by its only reported endogenous location, the hypothalamus, long implicated in control of temperature. It is premature to hypothesise a mechanism or locus of action of neurotensin in cold tolerance. The fact that central administration of this peptide has marked effects on both maintenance of body temperature and the duration of pentobarbital-induced sedation[11] indicates that it can affect the central nervous system directly. This is supported by lack of action of this peptide in both these situations after peripheral administration. The failure to find activity in these tests after peripheral administration of substantially greater amounts than are active centrally suggests the site of action of neurotensin lies within the blood–brain barrier. But the possibility that neurotensin i.c. exerts its effects by acting directly on cerebral vasculature or on central mechanisms that control peripheral vasomotor changes cannot be excluded. It is interesting that substance P, an unadecapeptide that also induces hypotension after intravenous administration[14,15], has no effect on thermoregulation in a cold environment after central administration. In a similar manner, SRIF, a tetradecapeptide, failed to affect cold tolerance significantly. These findings suggest specificity of the neurotensin effect we have described.

In our experiments with mice, we found that even i.v. neurotensin at 100 μg kg^{-1} failed to induce cold intolerance. On the other hand, Carraway and Leeman found in the rat that less than 2 μg kg^{-1} given intravenously produces cyanosis and hypotension[2]. We did not measure possible blood pressure changes in our mice, but constant observation revealed no cyanosis. Species differences may account for this discrepancy.

Table 3 Effect of intravenous neurotensin on cold-induced (4 °C) hypothermia in the mouse

Substance	Rectal temperature (°C)±s.e.m.				
	0 min	30 min	60 min	90 min	120 min
Saline ($n = 16$)	38.6±0.172	37.1±0.191	36.8±0.242	36.4±0.358	35.8±0.522
Neurotensin 10 μg kg^{-1} ($n = 8$)	37.8±0.213	37.0±0.245	36.8±0.281	36.7±0.313	36.3±0.384
Neurotensin 30 μg kg^{-1} ($n = 8$)	39.0±0.152	37.3±0.243	37.1±0.543	36.0±1.22	35.4±1.14
Neurotensin 100 μg kg^{-1} ($n = 8$)	38.8±0.137	37.4±0.195	37.3±0.177	36.8±0.205	36.5±0.288

Species differences may also explain the null effect of TRH in our study, which contrasts with its reported effects on thermoregulation in rabbit[12] and cat[13].

In the light of the evidence presented here, neurotensin can apparently be included in the growing list of peptides which seem directly to influence central nervous system function[16].

Pancreatic gastrin in foetal and neonatal rats

IT has been suggested[1,2] that pancreatic gastrin is stored in islet A_1 (or D) cells. There are, however, conspicuous histological and histochemical differences between antral gastrin cells and A_1 cells, indicating the storage of different peptide molecules in these two types of cell[3,4]. Furthermore, pancreatic tumours producing gastrin are composed of cells that have no features in common with A_1 cells but often resemble antral gastrin cells[5,6]. We have now tested a large number of gastrin antisera, most of which were specific for the C-terminal, bioactive, sequence of gastrin-17, on both unfixed and formaldehyde-fixed tissue, and found that all antisera reacted with antral gastrin cells but not with A_1 cells. Also, radioimmunoassayable pancreatic gastrin occurs at levels far below those expected if the A_1 cells stored gastrin[7]. We conclude that if gastrin-like peptides occur in the pancreatic A_1 cells they must be devoid of the bioactive, C-terminal sequence. While studying the ontogeny of the rat gastrin cell we have, however, found, at a certain stage of development, true gastrin cells in the pancreas.

In the pancreas, gastrin-immunoreactive cells were observed at day 18 of foetal life (the earliest stage studied). The cells occurred both in islets and scattered among exocrine cells (Fig. 1*a*). The gastrin cell number increased up to day 4 after birth, when it slowly began to decrease. A few pancreatic gastrin cells were seen in 12- to 20-d-old rats but at this stage they were usually restricted to the ductal epithelium. In rats older than 20 d gastrin cells were never observed in the pancreas (except for occasional cells in the epithelium of large excretory ducts). During all stages the gastrin cells seemed uniformly distributed between the tail and the duodenal lobe.

In the duodenum of adult rats gastrin cells were scarce[11]. The duodenum of rat foetuses contained, however, a fair population that could be detected at a foetal age of 18 d. Like the pancreatic gastrin cells, these cells increased in number until a few days after birth when their number (per unit area) started to decrease. In the antral mucosa, gastrin cells could be detected only after birth[11]. Cells, with an ultrastructure indistinguishable from that of the presumed gastrin cells (G cells) of rat antral mucosa, were detected in antral and duodenal mucosa and in pancreas of neonatal rats (4-d-old) (Fig. 1*b*). The distribution pattern and number of G cells was in good agreement with that of the gastrin-immunoreactive cells. Cells with an ultrastructure reminiscent of G cells have previously been detected in cultures of neonatal rat pancreas[12,13]. Such cells were not found in

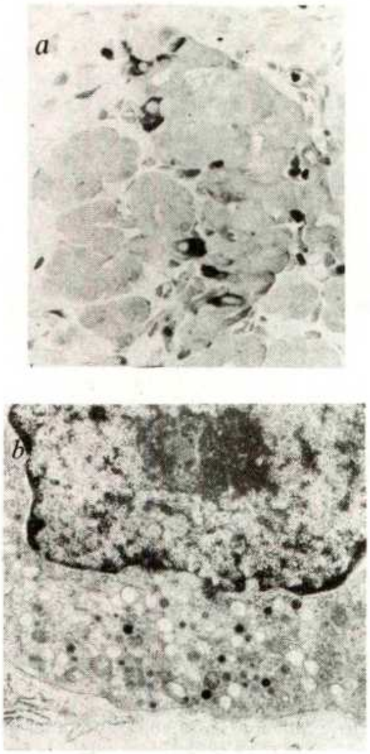

Fig. 1 *a*, Pancreas from 19-d-old rat foetus, showing an islet containing several peripheral gastrin cells (immunoperoxidase staining; ×217). *b*, Pancreas from 4-d-old rat, showing a typical G cell (glutaraldehyde-fixed, osmicated specimen; ×7,800). Foetal rats were removed at 18, 20 and 21 d of gestation, and newborn and young rats taken 1–30 d after birth. Adult male and female rats (200–300 g) were also used. After diethyl ether anaesthesia the antropyloric region, the duodenum and the duodenal lobe (that is, the portion of the pancreas that is adjacent to the duodenum) and the tail of the pancreas were dissected out. The specimens were freeze-dried and fixed with formaldehyde vapour. Paraffin sections were subjected to an indirect immunohistochemical method for demonstrating gastrin immunoreactivity[3]. Gastrin antisera numbers 2604, 2609, 2720 and 4562 (ref. 8) were used at dilutions 1:20, 1:40, 1:80 and 1:640, respectively. As a specificity control, these antisera were inactivated by the addition of synthetic human gastrin I (100 μg per ml diluted serum). Thus inactivated antisera failed to produce immunohistochemical staining. Samples for radioimmunoassay were taken from the same locations in 4- and 20-d-old and adult rats and extracted for 25 min in boiling redistilled water. The extracts were stored in the deep freeze until analysis. Each extract was analysed in triplicate at six different dilutions. Dilution curves for all extracts were identical with the standard curve. Gastrin was measured with antiserum 2604–8 (ref. 8). This antiserum is specific for the bioactive, C-terminal sequence of gastrin-17 and binds components I, II and III with equimolar potency[9]. It reacts very poorly with cholecystokinin, the molar ratio between ID_{50} of synthetic human gastrin-17 and highly purified porcine cholecystokinin being <0.006. Monoiodinated gastrin-17 was used as tracer[10] and synthetic human gastrin-17 as standard.

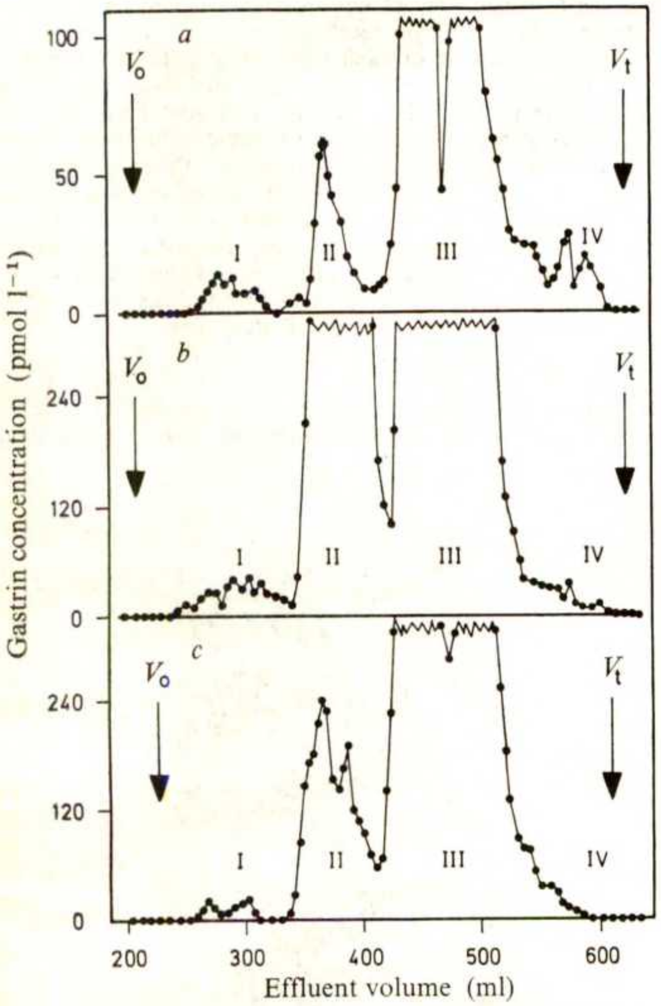

Fig. 2 Elution diagrams of gastrin components from extracts of *a*, pancreas (3.2 μEq synthetic human gastrin-17 per g wet weight tissue); *b*, duodenum (10.5 μEq synthetic human gastrin-17 per g wet weight tissue); and *c*, antrum (18.4 μEq synthetic human gastrin-17 per g wet weight mucosa). Pancreas and duodenum were from 4-d-old rats, antral mucosa from adult rats. The tissues were frozen and then boiled for 25 min in redistilled water, homogenised and centrifuged. The supernatants were applied to Sephadex G-50 superfine columns (25 × 2,000 mm) and eluted with 0.25 mol l^{-1} NH_4HCO_3 at 4 °C in 3.0 ml fractions at a flow rate of 15.0 ml h^{-1}. The columns were calibrated with albumin (void volume V_0), $^{22}NaCl$ (total volume V_t), highly purified human gastrin-34 (component II), gastrin-17 (component III), and gastrin-14 (component IV) donated by Professor R. A. Gregory and Dr Hilda Tracy (Liverpool). Roman numbers I–IV indicate elution volumes of components I–IV from calibration studies.

the pancreas or duodenum of adult rats. As gastrin cells are rare in the duodenum of the adult rat[11], however, they may therefore have escaped attention in the electron microscope.

Gastrin immunoreactivity was observed to a considerable extent in the duodenum (10.5 μEq synthetic human gastrin-17 per g wet weight tissue) and pancreas (3.2 $\mu g\, g^{-1}$) of 4-d-old rats. The level of antral gastrin at this age was considerably lower (0.9 $\mu g\, g^{-1}$). For comparison, the concentration of antral gastrin in the adult rat was 18.4 $\mu g\, g^{-1}$. In the pancreas of 20-d-old rats no gastrin could be detected.

Gel-permeation chromatography revealed that gastrin immunoreactivity from the pancreas (and antrum) of 4-d-old rats eluted in the same pattern as gastrin from antral mucosa of adult rats (Fig. 2). In the duodenal extracts (4-d-old rats) the proportion of component II (gastrin-34) was greater (Fig. 2) than in the antral and pancreatic extracts.

We refer to the immunoreactive pancreatic cells as gastrin cells because: like antral and duodenal gastrin cells they can be demonstrated in sections from formaldehyde-fixed, paraffin-embedded specimens; they can be demonstrated using a variety of gastrin antisera, of which most are directed against the bioactive C-terminal portion of gastrin-17 (ref. 9); in extracts of foetal and newborn rat pancreas significant quantities of gastrin have been demonstrated by radioimmunoassay; the extracted gastrin eluted by gel-permeation chromatography in a pattern indistinguishable from that of antral gastrin.

Little is known about the ontogeny of gastrin cells. Using a bioassay procedure Zelenkova and Gregor[14] observed that in the rat antral gastrin appears first after weaning. We have reported previously[11] that antral gastrin as revealed by immunohistochemistry and radioimmunoassay, appears far earlier. Also, in rabbit[15] and man[3] gastrin cells have been shown to occur prenatally. In the 18-d-old rat foetus, gastrin cells were found in the duodenum and in the pancreas but not in the antrum. Thus, gastrin cells do not seem to appear first in antral mucosa but instead make their debut in the duodenum and in the pancreas. The role of this early gastrin is unknown, but it may exert trophic actions on the pancreas and/or the gastrointestinal tract[16].

Kinetics of reaction in calcium-activated skinned muscle fibres

A PROCEDURE reducing the diffusion-limited equilibration time of the Ca^{2+} concentration within skinned muscle fibres[1] activated from outside has been used to investigate the kinetics and the stoichiometry of Ca^{2+} in the process of tension development in frog skeletal muscle. The diffusion problems are minimised by activating (or relaxing) the myofibrillar preparation in a solution with a very high Ca^{2+}-buffering capacity compared to that of the fibre as a whole[2,3] (solution in the interfilament space, sarcoplasmic reticulum, myofibrillar proteins); by using only thin fibres; and by using an efficient *p*H buffer (TES: *N*-Tris (hydroxymethyl) methyl-2-aminoethanesulphonic acid) and a

Table 1 Apparent binding constants of the ligands used in the bathing solutions

Ligand	Cation	Average apparent binding constant (M^{-1})	Experimental conditions	Observations
ATP	Mg^{2+}	5,800±400	Measured at *p*H 7.10	Very good agreement with the calculated[3] apparent binding constant based on the "absolute" values reported by Taqui and Martell[28] and Phillips *et al.*[29], for the same temperature values and ionic strength.
EGTA (molecular weight 380.4)	Ca^{2+}	$(5\pm0.5)\times10^6$	Measured at *p*H 5.7–5 8, presence of TES 0–250 mM, extrapolation[30] to *p*H 7.10	The measured apparent binding constant at room temperature was ~ 20% higher and is in good agreement with the calculated[30] value based on the results of Schwarzenbach[7] obtained at room temperature and in the presence of 0.1 M K^+.
	Mg^{2+}	25±5	Measured at *p*H 7.10	The measured value at room temperature was 46±6 M^{-1} and is in very good agreement with the calculated value based on the result of Schwarzenbach[7] (see above).
HDTA (molecular weight 348.4)	Mg^{2+}	8±1.5	Measured at *p*H 7.10	Agreement with Anderegg[13].
	Ca^{2+}	6.5±1		
TES	Mg^{2+}	≃ 1	Measured at *p*H 7.10	Agreement with Good *et al.*[31].
	Ca^{2+}	≃ 1		
Creatine phosphate (CP)	Mg^{2+}	12±1.5	Measured at *p*H 5.0–5.10, extrapolated to *p*H 7.10	Considering that at *p*H 7.10 the creatine phosphate is divalently charged, the apparent binding constant is in agreement with the value reported by Smith and Alberty[32] for room temperature and 0.1 M ionic strength.

The determinations were made with a *p*H metric method at $[K^+] = 130$ mM, $[Na^+] = 40$ mM, temperature 1±0.5 °C.

high ATP concentration in conjunction with a powerful ATP regenerative system (creatine phosphate (CP) and creatine kinase (CK)). Great care has been taken in preparing bathing solutions with similar concentrations of monovalent metallic cations (~150 mM), protons (*p*H 7.1)[4] and $[Mg^{2+}]$ (~1 mM) (refs 5 and 6) to those *in vivo.* For this purpose, the apparent binding constants of the various ligands for Ca^{2+} and Mg^{2+} have been measured by a *p*H metric method (Table 1).

A first important observation is shown in Fig. 2*g*, where a myofibrillar preparation was activated in a solution with a high Ca^{2+}-buffering capacity around *p*Ca 3 (using NTA:nitrilotriacetate)[7,8] after being equilibrated in 0.1 mM EGTA (ethanedioxy*bis*(ethylamine)tetraacetate). Although the fibre is activated from outside[9] force develops rapidly, with a time constant similar to that observed *in vivo* during a tetanus[10,11]. This record can only be used for qualitative interpretations since here diffusion still remains a problem.

In the other experiments (Figs 1 and 2*a–f*), the Ca^{2+}-buffering capacity of the interfilament space has been lowered by incubating the myofibrillar preparation in 0.15 mM EGTA and by adding 10 mM caffeine to all bathing solutions[12]. Subsequently, the preparations were activated in 50 mM EGTA+CaEGTA. To maintain other ionic species constant during the tension response, HDTA (hexamethylenediamine-*NNN′N′*-tetraacetate)[13] was used. The loading of the skinned fibre preparation with the Ca^{2+}-sensitive photoprotein aequorin[14] has indicated that for the conditions in Fig. 2*a–f*, the myofibrillar Ca^{2+} concentration will practically equilibrate within 150 ms of the change of solutions (unpublished).

The results presented in Figs 1 and 2*a–f* were obtained from the same preparation in order to reduce their scatter. These results are typical of more than 20 experiments. For the kinetic analysis it is important to note that for the experimental conditions described in the legends, the absolute steady-state level for a given $[Ca^{2+}]$ has a much more pronounced tendency to change[15–17] (dropping by 3–8% from one contracture to the next) than the time course of the tension development, which remains essentially the same even after 7 activation–relaxation cycles (see Fig. 2 and legend). The relative steady-state isometric tension levels, unlike the absolute force values associated with different $[Ca^{2+}]$ are not affected by repetitive contractures and this relationship is illustrated in Fig. 1. A fourfold increase in $[Ca^{2+}]$ (from *p*Ca 6.5 to 5.88) corresponds to an increase of the relative tension from about 9 to 92%. Since the minimum number of calcium ions involved in the process of tension activation is suggested by the smallest integer *n* which satisfies the

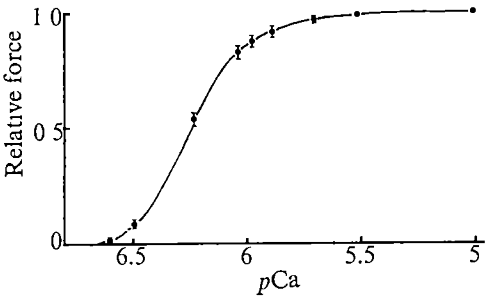

Fig. 1 Dependence of the relative steady-state isometric tension response on $[Ca^{2+}]$ expressed as *p*Ca ($-\log[Ca^{2+}]$) in skinned fibres from the iliofibularis muscle of *Rana esculenta.* The experimental values (●) have been obtained on the same preparation, from 25 cycles of contraction (some of which are shown in Fig. 2), to reduce the scatter indicated by the vertical bars. The relative force values have been corrected for the drop in tension due to multiple activation–relaxation cycles (see Fig. 2 and text). The continuous solid line represents the theoretical prediction from equations (1)–(3) for the constants mentioned in the text. The isometric tension has been measured with an RCA force transducer The recording system had a sensitivity of 0.3 mV μN^{-1}, a resonant frequency of 150 Hz and a compliance of 1.4 cm N^{-1}. The bathing solutions (volume 3 ml) have been changed using a method similar to that of Hellam and Podolsky[2,3,16]. All but the incubating solution were covered to avoid volume changes. The solutions contained substances of reagent grade (mM): $[Ca\text{-}EGTA^{2-}] + [EGTA^{2-}]$, 50; $[Na_2\text{-}CP]$, 10; $[Na_2\text{-}ATP]$, 8; [Caffeine], 10; [TES], 140 Creatine kinase 10 U ml^{-1}. The *p*H was adjusted to 7.10±0.01 with KOH at 1 °C so that the final value for $[K^+]$ was 137.5±2 mM. The concentration of the added $MgCl_2$ varied slightly (within 1 mM) in order to maintain a free Mg concentration of 1 mM in each solution, based on the apparent affinity constants shown in Table 1. To improve the accuracy of the relative and absolute $[Ca^{2+}]$ determinations in the bathing solutions, the free EGTA concentration has been always retitrated in each solution after the experiments[27], and care has been taken to maintain the *p*H in all solutions within 0.01 units. Temperature: 2 ± 0.5 °C.

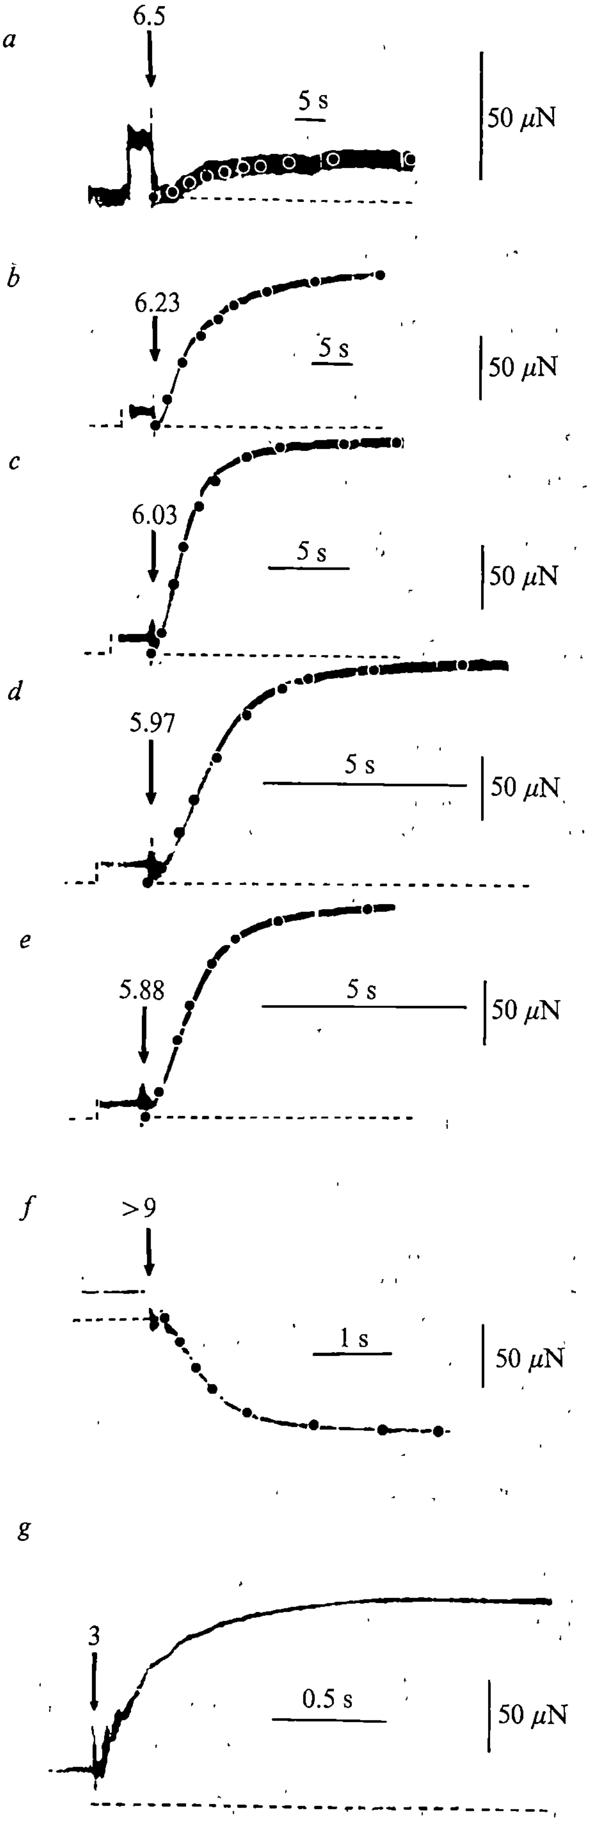

Fig. 2 *a–e* Time course of the 2nd, 4th, 5th, 6th and 7th isometric tension responses in the same frog myofibrillar bundle as for Fig. 1, when activated in EGTA containing solutions (for composition see legend Fig. 1). Diameter 50 μm, length 1.2 mm; sarcomere length close to its value *in situ*, 2.3–2.5 μm. The *p*Ca values of the activating solutions are shown above the arrows which indicate the moment of immersing the preparation in the contracting solution. Before each contracture, the preparation has been equilibrated for at least 4 min in a relaxing solution which had the same free cationic composition as the activating solution with the exception of $[Ca^{2+}]$. The relaxing solution contained 50 mM $HDTA^{2-}$ and 0.15 mM free $EGTA^{2-}$ in order to balance the activating solutions which contained 50 mM $Ca\text{-}EGTA^{2-} + EGTA^{2-}$. The contamination level of calcium was about 10 μM, due mainly to TES, caffeine and HDTA, so that the *p*Ca value in the myofibrillar preparation before the activating step was around 8. The artefact which appears in front of the arrows is due to the movement of the myofibrillar bundle through the solution–air–solution interface. The temperature of the solutions and of the air around the preparation has been maintained to 2 ± 0.5 °C throughout the experiment. During the first several high contraction cycles, the maximum tension had a tendency to drop by about 6% per cycle. After the 12th cycle, the steady-state values dropped less. The rate of tension development for a given *p*Ca was more stable, decreasing for example only by 8% between the 5th and the 12th cycle of contraction, but maintaining very accurately the same shape. *f*, Time course of the relaxation (20th cycle) of the preparation in a solution containing 50 mM free $EGTA^{2-}$ ($pCa > 9$) after being contracted for 3 min in a similar solution as the relaxing one (see above), but in which $EGTA^{2-}$ was replaced by $HDTA^{2-}$ (see text). This contracting solution contained 10 μM unbuffered Ca in addition to the contamination level of about 10 μM. *g*, Time course of the tension development in a frog myofibrillar bundle (diameter 45 μm, length 1.5 mm, sarcomere length about 2.3–2.5 μm) at 4 °C, when activated in a solution containing (mM): NTA, 30; TES, 100 (*p*H 7.10±0.01 with KOH); $CaCl_2$, 27.15; $MgCl_2$, 6.3; K^+, about 115; Na_2-ATP, 6. In this solution the level for both $[Ca^{2+}]$ and $[Mg^{2+}]$ should be close to 1 mM (refs 7, 8). The preparation had been previously equilibrated for 5 minutes in a relaxing solution containing (mM): TES, 100 (*p*H 7.10±0.01 with KOH); KCl, 86; Na_2-ATP, 6; $MgCl_2$, 6.12; EGTA, 0.1, in which the free Mg concentration should also be about 1 mM. The dashed lines represent the level of the isometric tension in the solution before the activating (*a–e* and *g*) or the relaxing (*f*) step. The solid dots (●) superposed on the experimental records *a–f* are the predicted values for the relative tension development from the kinetic scheme presented in the text.

inequality $R^n \geq 100$ (R being the ratio between the free calcium concentration corresponding to the relative tension of 91% and that corresponding to 9% relative tension)[18], it follows that in order to explain the experimental results plotted in Fig. 1, where $n = 4$, one has to assume at least 4 Ca^{2+} per 'functional unit'.

Figure 2*a–e* is a set of experimental tension records obtained as a result of a rapid increase of $[Ca^{2+}]$ in the myofibrillar bundle by the procedure described. First, up to $[Ca^{2+}] \simeq 1.2$ μM tension develops much slower than the expected time for $[Ca^{2+}]$ equilibration within the preparation (< 150 ms, see above) and this provides a good resolution for the kinetic analysis. The fact that the relatively slow development of tension here is not due to a simple physical process such as diffusion is supported by the large variation of the apparent rate of relative tension development for different experimental conditions. Second, all the tension transients in Fig. 2*a–e* are S-shaped, that is, the maximum rate of tension development is reached a significant time after the moment of activation. This observation suggests that at least two relatively slowly equilibrating steps are involved in the chain of reactions leading to the development of tension[3,19,20]; otherwise the curves would rise exponentially in time. A third important observation to be made is that the rate of tension development as indicated by the inverse value of the time required to reach 50% of the steady-state level, rises faster than the increase in the free calcium concentration over the *p*Ca range shown in Fig. 2*a–e*. For an increase of 4 times in Ca^{2+} (from *p*Ca 6.5 to 5.88) the half time for the tension development decreases sevenfold. This alone suggests that at least one of the slowly equilibrating steps of reaction must involve at least 2

Ca^{2+} apparently, while the other involves at least 1. This third observation taken together with the fact that the relative tension increases over the same *p*Ca range 6.5–5.88 such as to require at least 4 Ca^{2+} (see above) suggests that more than 4 Ca^{2+} must be involved per functional unit to produce tension. Finally, the relaxation in a 50 mM free EGTA solution (*p*Ca > 9) of the same myofibrillar preparation, which has been previously equilibrated in a solution containing about 20 µM unbuffered Ca (Fig. 2*f*), can be approximated with an exponential having a rate constant of $-1.75\ s^{-1}$, a value similar to that obtained by Huxley and Simmons[11] *in vivo*. The time course of the relaxation is considerably faster than the time course of the activation at *p*Ca 6.5–5.88, and this implies that an additional Ca^{2+} must be involved in a faster step of reaction, following the rate-limiting steps for activation. In addition, Fig. 2*g* suggests that, taken separately, the reaction steps which follow those in which Ca^{2+} is directly involved for the activation of tension should be considerably faster than the relatively slowly equilibrating steps strongly controlled by Ca^{2+} at *p*Ca > 5.5.

A detailed quantitative analysis of the results such as those presented in Figs 1 and 2, based on the assumption of reversible calcium reactions and on the suggestion that the isometric tension response in these fibres is directly correlated with the interaction between the myofilaments[10,11], has ruled out reaction schemes involving less than 6 Ca^{2+} per functional unit. The simplest scheme of reaction to explain the results for *p*Ca > 5.5, which can also be connected with recent biochemical data is one in which the isometric tension response, *P*, is proportional to the concentration of a product $Ca_4A{-}MCa_2$, resulting from two independent reaction schemes, each one involving one slowly equilibrating step of reaction

$$A \underset{\text{rapid}}{\underset{k_{-1}}{\overset{k_1[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca}A \underset{\text{rapid}}{\underset{k_{-2}}{\overset{k_2[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca_2}A \underset{\text{rapid}}{\underset{k_{-3}}{\overset{k_3[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca_3}A \underset{\text{slow}}{\underset{k_{-4}}{\overset{k_4[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca_4}A \tag{1}$$

$$M \underset{\text{slow}}{\underset{k_{-5}}{\overset{k_5[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca}M \underset{\text{rapid}}{\underset{k_{-6}}{\overset{k_6[\mathrm{Ca}]}{\rightleftharpoons}}} \mathrm{Ca_2}M \tag{2}$$

and

$$P \propto [\mathrm{Ca_4}A{-}M\mathrm{Ca_2}] \propto [\mathrm{Ca_4}A]\cdot[\mathrm{Ca_2}M] \tag{3}$$

where $A-M$ is the tension functional unit containing the two types of Ca^{2+} reacting sites. The value of k_{-6} has been chosen such as to correspond to the rate constant of the relaxation, that is $1.75\ s^{-1}$, and the value for k_{-4}, suggested by the slowest rate of rise for tension (Fig. 2*a*), was chosen as $0.06\ s^{-1}$. The values for the other parameters used for explaining the experimental results in Figs 1 and 2 are: $k_{-1}, k_{-2}, k_{-3} \gg 15\ s^{-1}$; $100K_1 < K_2$; $10^4K_3 < K_4$; $K_1K_2 = 7\times10^{11}\ M^{-2}$; $K_3K_4 = 2.02\times10^{13}\ M^{-2}$ ($K_i = k_i/k_{-i}$ for $i = 1,2,3,4$); $k_5 = 9.44\times10^5\ M^{-1}s^{-1}$; $k_{-5} = 8.75\ s^{-1}$; $k_6 = 3.2\times10^8\ M^{-1}\ s^{-1}$. The predictions of this kinetic scheme have been superposed over the experimental results in Figs 1 and 2*a–f*. One can see that the agreement between theory and experiment is good.

Recent experiments suggest that the skeletal muscle in vertebrates might have a Ca^{2+} control mechanism of contraction linked with both myosin and actin filaments[21–24]. There is also evidence that the actin control could involve 4 Ca^{2+} per troponin[25,26]. The kinetic scheme presented here based solely on experiments using skinned frog muscle fibres in which $[Ca^{2+}]$ has been rapidly changed can be attractively connected with this new biochemical evidence, and suggests in addition that the myosin control in frog might involve two Ca^{2+} per functional unit.

I thank Professor H. Ch. Lüttgau for continuous interest and support, Professor Sir Andrew Huxley for his stimulating comments on the manuscript, Dr P. C. Caldwell for his constant encouragement and Dr C. C. Ashley for providing the aequorin. This work was supported by the Deutsche Forschungsgemeinschaft.

X-ray titration of binding of β,γ-imido-ATP to myosin in insect flight muscle

WE have attempted to establish a correlation between the binding of an ATP analogue, β,γ-imido-ATP (hereafter termed imido-ATP), and a structural change induced in muscle in the presence of this analogue. Imido-ATP binds tightly at the enzymatic site of myosin, but is not hydrolysed there[1]. When applied to glycerol-extracted muscle, it binds to the myosin *in situ* without causing the muscle to relax—that is, a ternary actin–myosin–nucleotide complex is formed[2]. Muscle fibres in this condition have the same mechanical stiffness as in rigor, but their zero tension point is displaced to a slightly greater muscle length, and both X-ray diffraction and electron microscopy indicate that the conformation of the attached myosin has altered, as if the head was rotated relative to the actin[2–5].

Unfortunately both structural signs can be faulted, the electron microscopy because of the possibility of fixation or postfixation changes[6], and the X-ray diffraction because of the long time which was used to obtain the required exposures[2,4]. We have tried to overcome these objections by observing diffraction changes within a short time after the nucleotide was added, and checking their relevance to the nucleotide binding by their relationship to the concentration used—that is, to obtain an X-ray titration of the nucleotide binding. For this purpose, the most powerful source of X rays available was used. The experiments were carried out at the EMBL synchrotron radiation facility at the DESY synchrotron, Hamburg[7,8], on glycerol-extracted dorsal longitudinal flight muscle from *Lethocerus cordofanus* dissected into bundles of 25 to 40 fibres. These were mounted on a mechanical apparatus in which their stiffness and tension could be monitored[2], and immersed in a neutral, calcium-free buffer at low ionic strength at 13–15 °C (20 mM imidazole, 10 mM NaN_3, 4 mM EGTA, 10 mM $MgCl_2$, pH 6.9, as described previously[4]). An intense monochromatic X-ray beam of wavelength 1.5 Å was passed through the sample and the resultant small angle diffraction pattern from the hexagonal lattice of myosin and actin filaments was recorded at 80-cm specimen–counter distance using a position-sensitive gas detector with a resolution of approximately 0.2 mm full width at half maximum (FWHM) (ref. 9).

The two strongest diffraction peaks on the equator deriving from the basic 530 Å lattice periodicity and designated $10\bar{1}0$ and $20\bar{2}0$ were readily recorded in conveniently short times. By slight displacement of the beamstop, it was possible to observe one $10\bar{1}0$ and both $20\bar{2}0$ diffraction peaks clearly (Fig. 1*a*). The entrance slit of the detector was opened wide (2 mm) so that the entire width of the equatorial peaks were received; the efficacy of this was checked by comparison of the counting scans with densitometer traces from films of the same specimens. Data were usually collected in 300 s, representing $0.5–1.0\times10^4$ counts per channel at the peak of each reflection. The intensity of each of the three peaks was estimated from the product of its peak height above background and half-height width. The $20\bar{2}0/10\bar{1}0$ intensity ratio R was calculated from the mean value of the two outer peaks, $R = (20\bar{2}0_{\mathrm{L}}+20\bar{2}0_{\mathrm{R}})/2\times(10\bar{1}0)_{\mathrm{R}}$.

In rigor (that is, in the absence of nucleotide) R was slightly greater than unity (mean ±s.e. 1.26±0.03; $n = 27$), which agrees with previous estimates[10]. On addition of sufficient imido-ATP to ensure binding to myosin[2], the ratio fell by approximately one-third of its value (Table 1). The widths of the peaks did not alter significantly. Two-thirds of the change in R occurred before the mid-time of the first measurement (3–6 min after addition of the nucleotide), the remaining change occurring gradually over the ensuing 20 min. On removal of the nucleotide, the change was partially reversed (mean recovery 60±10%; $n = 10$); again, approximately two-thirds of the reversal occurred 5–7 min after the start of removal and the rest over the following 30 min. Sequential increases of nucleotide concentration at 10-min intervals produced a graded increase in R. The data fitted a hyperbolic binding curve (Fig. 1*b*) with a dissociation constant (Table 1) similar to that obtained by direct binding measurements[2]. On removal of the nucleotide after the 2-h immersion necessary to obtain this curve, the ratio reverted towards the rigor value, as in the shorter immersions.

Fig. 1 *a*, Trace of output from position-sensitive detector aligned along the equator of the diffraction pattern from insect flight muscle in rigor. The $10\bar{1}0$ peak on the left-hand side of the diagram is elevated by the background and interrupted by the beamstop; it was not used for calculation. *b*, Change in R on addition of β,γ-imido-ATP in a single experiment. The continuous line is the best fitting hyperbola ($K_d = 65\pm6$ μM, $\Delta R_{max} = 0.31\pm0.01$) (ref 18).

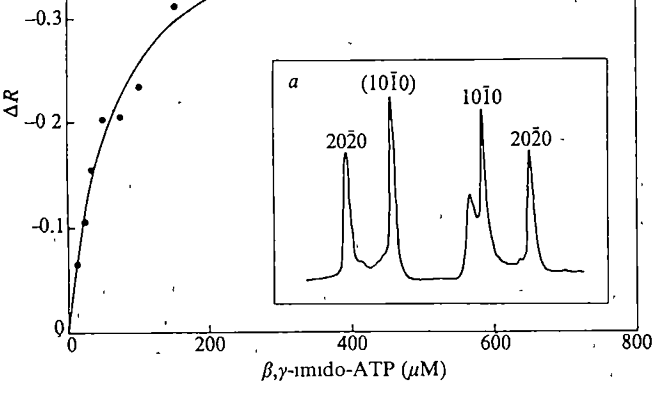

Table 1 Changes in R on adding various ligands to insect flight muscle

Ligand	ΔR
β,γ-imido-ATP	
500–1,700 μM	−0.34±0.05 (10)
Limiting value*	−0.41±0.03 (46); $K_d = 90\pm19$ μM
ADP 200–400 μM†	−0.01±0.01 (7)
Pyrophosphate	
600–1,200 μM	−0.17±0.03 (4)
Limiting value†	−0.25±0.04 (16); $K_d = 450\pm120$ μM
ATP 15 mM	−0.59±0.07 (5)

Mean ±s.e. cited; number of experiments in brackets. ΔR was calculated from the change in peak heights of the two reflections on adding the ligand.

* Calculated by hyperbolic fitting to the measurements at different ligand concentrations[18]. 10 mM Mg^{2+} present in all solutions except ATP, where 15 mM Mg^{2+} was added; pH 6.9, ionic strength=0.1, 14°C.

† 50–100 μM diadenosyl pentaphosphate was also added to these solutions to block adenylate kinase activity[20].

The effect of other ligands was also studied. ADP, in a concentration well above its known dissociation constant[11], had no significant effect on R (Table 1). Pyrophosphate reduced R by a smaller amount than imido-ATP at comparable concentrations. Its effect was graded over the range available, which was limited by the solubility of Mg-pyrophosphate. Application of a hyperbolic fit indicated that the full effect of binding pyrophosphate was probably greater than that observed, but still less than that for imido-ATP (Table 1). On removal of pyrophosphate the ratio reverted to or beyond its initial value (mean recovery 125±25%; $n = 4$).

In all these cases the 5-Hz stiffness (that is, muscle stiffness measured by the change in tension resulting from a small amplitude 5-Hz sinusoidal length oscillation) of the muscle remained high (approximately 20 mg per fibre % extension) in the presence of nucleotide, as expected from previous results[2]. On addition of ATP the muscle relaxed; the 5-Hz stiffness fell by a factor of four and could not be restored by extension. The ratio R fell by approximately half its value (Table 1) in agreement with previous observations[10]; the widths of the peaks did not alter. The effect was reversed by removal of the nucleotide (mean recovery 87±3%; $n = 3$).

During the course of each of these experiments, which lasted 3–15 h, the filament lattice spacing gradually decreased by approximately 5% (mean initial value 533±5 Å; $n = 5$; final value 510±4 Å; $n = 5$). Addition of any of the unhydrolysed ligands had little or no effect on the spacing.

These results show that within a short time of the binding of imido-ATP to myosin, a structural change occurs in the muscle, the magnitude of which is directly proportional to the amount of nucleotide bound. They do not show the nature of the change, since according to model studies either rotation of the attached myosin, redistribution of the locus of attachment along the actin filament or detachment of a proportion of the myosin from the actin would all cause such a change (refs 10 and 12, and K. C. Holmes, J. B. L. and R. T. T., unpublished). We believe that the third possibility is excluded by the retention of the muscle's stiffness and the high intensities of the actin-based layer lines in the presence of imido-ATP[2–4]. It is not possible to differentiate the other two possibilities. Whichever structural change is responsible, it certainly occurs quickly; the main objection to the X-ray diffraction evidence has been removed.

It is probable that the change in R produced by pyrophosphate has the same molecular origin, since electron microscopy[13] shows elements of the same changes occurring in the muscle. The observed concentration dependence agrees with that deduced from mechanical observations[14]. The failure of ADP to shift the ratio indicates that this nucleotide causes relatively little redistribution or rotation of the myosin; the outer layer lines of the X-ray diffraction pattern are also little altered by this ligand[15].

These results are also relevant to vertebrate skeletal muscle, since Lymn has shown that imido-ATP produces a large shift in the $11\bar{2}0/10\bar{1}0$ ratio in glycerol-extracted rabbit psoas fibres[16]. As imido-ATP does not reduce the 5-Hz stiffness of these fibres at a given tension[2], it is probable that this change is also due to a redistribution or rotation of attached myosin, rather than its release from the actin. If so, this invalidates the assumption that a change in R can be used to predict the proportion of myosin attached to actin[17,19].

In conclusion, we now have evidence that ligands which attach to the enzymatic site of myosin do alter either its position relative to the actin or the location of the actin to which it tends to attach. The effect is both rapid and specific, and may well be relevant to the state of the myosin during its contractile cycle.

Phosphorylation of troponin I and the inotropic effect of adrenaline in the perfused rabbit heart

THE regulation of contractile activity in cardiac muscle by changes in the intracellular Ca^{2+} concentration involves the regulatory protein system, consisting of tropomyosin and the troponin complex that is located in the I filament. Although the regulatory protein system of cardiac muscle is essentially similar in function to that of skeletal muscle, the components differ in the two tissues. Cardiac tropomyosin consists principally of α subunits, whereas the skeletal protein is composed of α and β subunits[1]. Troponin I, troponin C and troponin T are all specific for cardiac muscle in that they have different chemical and immunochemical properties from the corresponding skeletal muscle proteins[2–4]. In addition, cardiac troponin I and cardiac troponin C have been shown to have different amino acid sequences from their skeletal muscle counterparts[3,5].

Although rabbit cardiac troponin I shows considerable sequence homology with troponin I from fast skeletal muscle, it has an additional 26 residues at the N terminus[3]. The rapid phosphorylation of a serine at position 20 in this extra N-terminal part of the cardiac troponin I molecule is mainly responsible for the fact that the phosphorylation catalysed by cardiac cyclic AMP-dependent protein kinase is about 30 times faster with cardiac troponin I than with fast skeletal troponin I (ref. 4). When isolated immediately after death by stunning, a phosphate content of 2–3 mol mol^{-1} has been reported for cardiac troponin I, compared with 0.5–1.0 mol mol^{-1} for skeletal muscle troponin I (ref. 4). These differences suggest that the phosphorylation of troponin I may have a special significance for the regulation of the contractile activity of cardiac muscle. Further evidence for such a role indicates that there is a correlation between the contractile force developed on adrenaline application and the extent of phosphorylation of troponin I in the perfused rat heart[6].

We describe here investigations extending our studies on the enzymic phosphorylation of isolated rabbit cardiac troponin I to the perfused heart. We have attempted to relate the effects of adrenaline on the contractile activity of the perfused rabbit heart to the phosphorylation of specific sites on the troponin I.

The total phosphate content of rabbit cardiac troponin I varied with the conditions in which the heart was removed. Troponin I was immediately isolated by affinity chromatography[7] and, before analysis, was washed four times with 7.5% (w/v) cold trichloroacetic acid to remove non-covalently bound phosphate. Values of 2.1 ± 0.4 mol P per mol were obtained when hearts were removed immediately after death by stunning. If hearts were made anoxic by clamping the aorta for 30 s just before removal from the animal, similar or slightly higher values were obtained. If the rabbits were anaesthetised with pentobarbital, and troponin I subsequently isolated from hearts removed after freezing *in situ* in Wollenberger clamps chilled with liquid nitrogen, a value of 1.5 ± 0.2 mol P per mol troponin I was obtained.

Hearts removed rapidly from stunned rabbits, as described[8] for rats, were cooled for 15–20 s in ice-cold saline and perfused by the Langendorff procedure at 37 °C with modified Krebs–Henseleit buffer[9] in an apparatus fitted with a recirculation chamber similar to that described by Morgan *et al*[10]. Force and rate were recorded on a polygraph using a force transducer attached to a stainless steel hook in the apex of the heart At various times, the ventricles (about 4 g tissue) were cut rapidly from the heart and homogenised immediately in 30 ml of 9 M urea, 75 mM Tris-HCl, pH 8.0, 1 mM $CaCl_2$, 15 mM β-mercaptoethanol and the troponin I isolated by affinity chromatography[7]. During the 2–5 min initial equilibration period, cardiac troponin I contained 2.5 ± 0.4 mol P per mol. After 10–15 min perfusion, the phosphate content of troponin I fell to 1.5–1.6 mol P per mol and remained nearly constant for at least 100 min, during which heart rate and force also remained virtually unchanged.

Addition of 0.1–4.0 μM adrenaline to the perfusion media after an initial equilibration period of 15 min caused a rapid and dose-dependent increase in the force developed by the myocardium. Hearts were removed rapidly from the apparatus at the moment of peak force development, homogenised and troponin I isolated. Total phosphate content increased in parallel with increasing force, reaching a maximum of about 3 mol P per mol troponin I at 2 μM adrenaline, when the maximum contractile response was obtained (Fig. 1).

If troponin I was isolated 5–10 min after the maximum inotropic response when the contractile force had returned

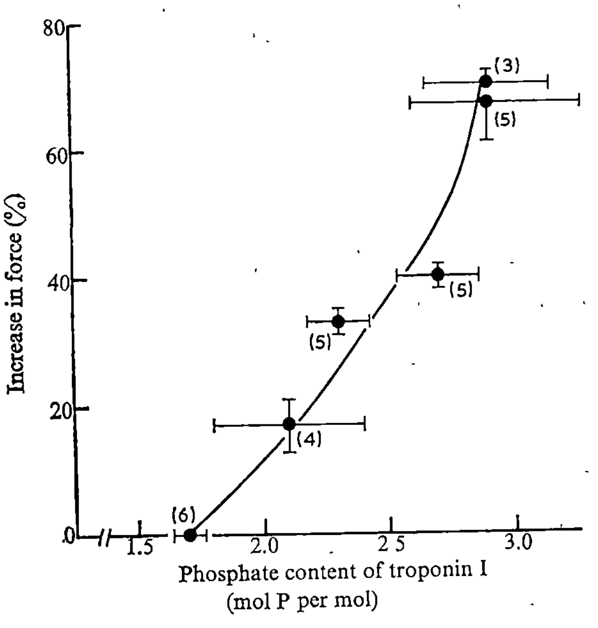

Fig. 1 Relationship between the phosphate content of troponin I and the increase in force developed in the perfused rabbit heart. Force changes were induced by adding 0.3–4.0 μM adrenaline to modified Krebs–Henseleit buffer (118 mM NaCl, 4.7 mM KCl, 2.5 mM $CaCl_2$, 1.2 mM $MgSO_4$, 0.2 mM KH_2PO_4, 0.5 mM Na_2 EDTA, 25 mM $NaHCO_3$ and 5 mM glucose) equilibrated with 95% O_2:5% CO_2 at 37 °C, *p*H 7.4. Hearts were first perfused for a 15-min equilibration period with normal buffer and then switched to buffer containing adrenaline. At the peak of the force change, the hearts were homogenised rapidly in buffered 9 M urea and troponin I isolated as described in the text. Phosphate content was calculated from total phosphate and nitrogen contents measured in duplicate samples of trichloroacetic acid-washed troponin I as described previously[15], using a molecular weight of 22,500 and a nitrogen content of 16% for cardiac troponin I. Figures in parentheses indicate number of hearts analysed.

to a value similar to that before adrenaline application, the total P content was similar to that obtained after equilibration but before addition of adrenaline. In the presence of β-adrenergic blockers such as propranolol, the inotropic response to adrenaline was inhibited and no significant rise in the phosphate content of troponin I occurred.

In a parallel series of experiments, the troponin I isolated after perfusion was washed repeatedly with cold 7.5% trichloroacetic acid to remove non-covalently bound phosphate and digested with cyanogen bromide. In control hearts perfused for 20 min, 90–95% of the total covalently bound phosphate was present in the N-terminal cyanogen bromide peptide of cardiac troponin I that contains residues 1–48 (ref. 3).

After 15–20 min perfusion with Krebs–Henseleit–bicarbonate medium containing phosphate labelled with ^{32}P, the N-terminal cyanogen bromide peptide became radioactively labelled. Of the ^{32}P recovered from a tryptic digest of this N-terminal peptide 80–90% was bound to serine 20, indicating that in the perfused beating heart there was rapid exchange between the pool of intracellular phosphate compounds and the phosphate on serine 20. If the troponin I was isolated at the peak of the inotropic response to adrenaline, the total incorporation of ^{32}P increased. The distribution of radioisotope in the peptides present in the cyanogen bromide digest of this troponin I indicated that 90–95% of the total ^{32}P incorporated was associated with the region of the cardiac troponin I molecule represented by residues 1–48.

These results suggest that at least three phosphorylation sites are significant for the function of cardiac troponin I in the rabbit. One of these, serine 20, is readily phosphorylated by cyclic AMP-dependent protein kinase. This site is usually phosphorylated in the perfused heart and readily exchanges with the intracellular phosphate pool. The precise location in the region consisting of residues 1–48, of the other two sites that must be phosphorylated when the total phosphate content rises to 3 mol mol^{-1}, is not clear. The sequence studies of Grand *et al.*[3], have shown that there are serines at positions 4, 20, 32, 37 and 39 and threonines at positions 26 and 46. Of these, serine 37 might be expected to be a site for phosphorylation by phosphorylase kinase by analogy with the action of this enzyme on troponin I from fast skeletal muscle of the rabbit[11,12]. As yet we have no information as to whether phosphorylation of serine 37 is involved in the inotropic response.

The results indicate, however, that the increase in the phosphate content of troponin I from about 2 mol mol^{-1} to 3 mol mol^{-1} is closely associated with the increase in contractile force obtained in cardiac muscle treated with adrenaline.

In troponin I from fast skeletal muscle, the N-terminal region is somehow involved with interaction with troponin C (ref. 13). Judging from the sequence data of Grand *et al.*[3], and the inhibition of the phosphorylase kinase-catalysed phosphorylation of cardiac troponin I by troponin C (ref. 4), a similar interaction probably occurs in the cardiac system. The introduction of negative charges by phosphorylation in the N-terminal region of the molecule, which contains an excess of positively charged amino acids, would be expected to alter the strength of the interaction with the negatively charged troponin C and thereby possibly change the affinity of troponin C for Ca^{2+}.

Preliminary investigations in this laboratory on natural and desensitised actomyosin indicate that after phosphorylation of cardiac troponin I by cyclic AMP-dependent protein kinase, the Ca^{2+} concentration required for 50% activation of the ATPase is increased, that is, the system is less sensitive to Ca^{2+} concentration (H. A. Cole and S.V.P., unpublished). This finding does not confirm those of Rubio *et al.*[14], who reported an increase in Ca^{2+} sensitivity of the ATPase of cardiac natural actomyosin on phosphorylation of troponin I.

Although our results do not permit us to say whether there is a direct casual relationship between the phosphorylation of troponin I and the inotropic effect of adrenaline, the events are undoubtedly closely associated in time. In view of the results of the enzymic studies, we suggest that one function of phosphorylation of troponin I is to act as a negative feedback system. Thus by reducing the sensitivity of the actomyosin ATPase to Ca^{2+}, it smoothes out the contractile response to the rise in intracellular Ca^{2+} which results from the action of adrenaline on the myocardium. A detailed account of this work will be published elsewhere in due course.

This work was supported in part by research grants from the MRC and the British Heart Foundation and carried out during the tenure by R.J.S. of a British American Research Fellowship of the American Heart Association and the British Heart Foundation.

Increase in human skeletal muscle lactate produced by fenfluramine

OUR recent hypothesis[1] that "anorectic agents" such as fenfluramine and mazindol owe at least part of their anti-obesity properties to a peripheral action on glucose metabolism by causing an increase in glucose uptake into skeletal muscle and a subsequent "wasting of calories" has been criticised[2] on the grounds that there is no information on the fate of the glucose so taken up, nor convincing evidence for an increase in metabolic rate with these drugs. We have now studied the effect of fenfluramine on lactate production in isolated human skeletal muscle, our previous work having shown no increase in glycogen levels[3] nor in carbon dioxide production[4]. An increase in lactate production would indicate metabolism of the glucose entering the cell under the influence of fenfluramine.

Human skeletal muscle was obtained at surgery for total hip joint replacement. The preparation and incubation of the tissue (in Krebs–bicarbonate buffer with added bovine serum albumin 2 mg ml^{-1} and glucose 16.67×10^{-3} M) was carried out using the method of Kirby, Leighton and Turner[5]. Muscle strips, wet weight 80–140 mg, were prepared from each sample and incubated in 2 ml of media containing (1) 100 μU ml^{-1} insulin, (2) 100 μU ml^{-1} insulin plus 100 ng ml^{-1} fenfluramine (previously shown to cause a maximal increase in glucose uptake[6]), (3) 100 μU ml^{-1} insulin plus 100 ng ml^{-1} amphetamine (amphetamine has no significant effect on glucose uptake into isolated muscle[3]). For each muscle sample two strips were prepared and used for control lactate determinations; they were not incubated Flasks were flushed with a mixture of 95% oxygen and 5% carbon dioxide for 10 s before incubation at 37 °C for 90 min. The lactate content of the muscle and the residual media were then determined.

The method for measurement of muscle and residual media lactate was based on that for blood lactate using NAD/LDH enzymes[7] and the Boehringer Mannheim Biochemica Test Combination for lactate. Muscle strips were removed from the media and homogenised for 5 min at 25,000 r.p.m. with a blade homogeniser in 2 ml of 0.6 M perchloric acid. The homogenate was centrifuged for 10 min at 3,000 r.p.m. and 0.2 ml of the supernatant used for the lactate determination. One millilitre of the residual medium was added to 1 ml of 0.6 M perchloric acid and centrifuged as before, 0.2 ml of the supernatant being used for the subsequent analysis, with the Biochemica Test Combination. A lactate standard (0.5 mM) was included as a blank. Preliminary work had demonstrated a linear relationship between absorbance at 340 nm and lactate concentration over the range 0–1.0 mM. Good reproducibility was obtained with the method, the mean of six muscle lactate determinations in strips from the same sample being 6.91 ± 0 21 mmol per kg wet weight of muscle.

Table 1 Lactate formed by isolated human skeletal muscle incubated with insulin, fenfluramine or amphetamine

Insulin*	Fenfluramine plus insulin: change compared with insulin alone*	Amphetamine plus insulin. change compared with insulin alone*
13.85	+1.04	−0.10
14.11	−2.09	+1.82
9.79	+2.33	+0.84
9.12	+0.23	−3.00
10.97	+0.10	−0.53
8.78	+1.67	+2.07
7.68	+1.07	−1:67
8.58	+1.53	−1.57
7.48	+2.53	−0.08
8.79	+1.07	−0.70
Means ± s.e m.	+0.95 ± 0.42	−0.29 ± 0.50
t	2 26	0.58
Significance	$P = 0.05$	NS

All values are means of two incubations
*mmol lactate per kg wet weight skeletal muscle per 90 min; 100 μU ml^{-1} insulin, 100 ng ml^{-1} fenfluramine and 100 ng ml^{-1} amphetamine.

The results (Table 1) demonstrate that fenfluramine produced an increase in muscle lactate concentrations. Amphetamine, which has no effect on glucose uptake, has no significant effect on lactate concentration. Further studies are needed to determine in more detail the metabolic fate of the glucose taken up under the influence of fenfluramine, but these results are further evidence for a peripheral metabolic mechanism in its anti-obesity activity.

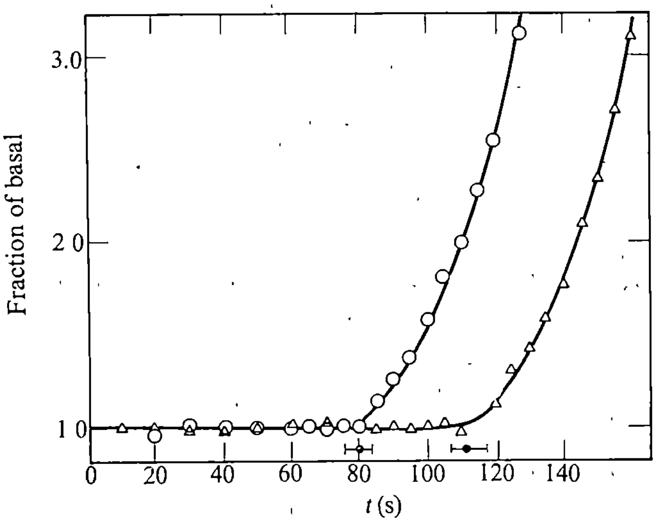
Ribosome slowed by mutation to streptomycin resistance

ALTHOUGH the basic mechanisms of protein synthesis are now rather well understood, particularly in *Escherichia coli*, it is less clear how the high accuracy of this process is achieved. (The error rate in protein synthesis in *E. coli* seems to be about one in 10^4 amino acid misincorporations (Edelman and Gallant, unpublished results, and our own unpublished data)). A major site determining accuracy in protein synthesis is the ribosome, and in addition to the ribosome-mediated effects on accuracy (*in vivo* and *in vitro*) of various metal ions, aminoglycoside antibiotics and organic solvents, there are ribosomal mutations which increase or decrease accuracy[2]. Certain mutations of the 30S ribosomal protein S12 conferring streptomycin resistance (the *strA* locus) enhance accuracy[3–5], whereas certain mutations in the S4 protein (the *ram* locus) are known to decrease accuracy[6]. The *strA* mutations are restrictive (reducing) in their effect on both missense and nonsense suppression *in vivo* and on miscoding *in vitro*[3], the *ram* mutation, on the other hand, has the opposite effect in both cases[6]. It is possible that it is the kinetics of polypeptide synthesis at the ribosome that determines accuracy and that the kinetics in turn are affected by the *strA* and *ram* mutations. Because the same transfer RNA (tRNA) discrimination kinetics that may determine accuracy may also contribute to the elongation speed, we have investigated the effect of mutation to streptomycin resistance on the speed of polypeptide elongation.

A simple kinetic model for discrimination of charged tRNA at the ribosome, like that described by Ninio[7], may be constructed. Such models imply directly that the more accurate a given ribosome, the slower is the transpeptidation reaction, and therefore the longer is the time required to synthesise a polypeptide of given length. In such a model one can attribute the specificity of message-directed polypeptide synthesis to the energy differences between binding of the complementary and non-complementary amino-acyl-tRNAs to the message codon and the amino-acyl site on the ribosome. Although we do not know what part of the elongation cycle time is required for transpeptidation, we expect that a mutation to streptomycin resistance, and therefore to a more accurate ribosome, should cause an increase in this time and thus a slowdown in elongation. We investigated this hypothesis by examining an otherwise isogenic set of independent spontaneous mutants, resistant to high levels of streptomycin, and have found that they do translate message at a slower rate.

Translation speed was determined by measuring the time required for the first newly synthesised β-galactosidase molecules to appear after induction of the lactose operon. This induction lag was measured in exponentially growing cultures by sampling every 5 (or 10) s into chloramphenicol to stop protein synthesis and assaying each of these samples for β-gal activity to generate an induction curve. The time between induction and the appearance of the first newly synthesised enzyme was determined to an accuracy of ±3 s. For the wild type, streptomycin-sensitive strain (IH79), the lag time we measured agrees with the results of Lacroute and Stent[9] and Kepes[10]. Although we are interested here in the relative differences in the measured lag times and not necessarily the absolute chain elongation times, the results of their experiments[9,10] indicate that the chain elongation time is at least 90% of the lag time (see also our unpublished work).

Fig. 1 Measurement of lag time to first completed β-galactosidase molecule (β-gal). Cultures of a lac permease negative (derivative of W1485) K12 strain, IH79(Str^S), and a spontaneous mutant derivative to streptomycin (200 µg ml^{-1}) resistance, IH82, were grown in glycerol minimal medium at 37 °C to a well-established exponential phase and then induced at $t=0$ by adding isopropyl-β-D-thiogalactopyranoside to a concentration of 1.0 mM. The cultures were sampled every 5 s by taking 0.5 ml into test tubes containing 0.5 ml of a solution (1.0 mg ml^{-1}) of chloramphenicol in distilled water These samples were then assayed for β-galactoxidase activity. Cell lysis was accomplished with chloroform and β-gal activity measured by hydrolysis of orthonitrophenol-β-D-galactopyranoside at 37 °C (ref. 8). The data are reported here in terms of the uninduced level of β-gal. From the observed point to point variation in the measured basal level (points before 80 s, for example) and by repeating the experiment several times we determined the inherent error in specifying the intercept and estimate that the time lag was measured to an accuracy of ±3 s. △, IH32, streptomycin resistant; ○, IH79, streptomycin-sensitive.



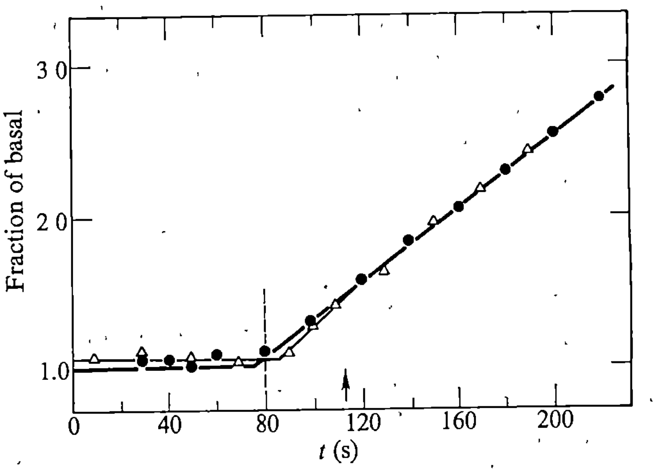


Fig. 2 Induction curves for IH79 and IH82 with actinomycin D. The conditions and sampling procedures for the chloramphenicol experiments were as described in the legend to Fig. 1. The cultures for the actinomycin experiments were treated by resuspension at 37 °C in EDTA–Tris buffer[13] (1 mM EDTA, 0.12 Tris, 1 mM Na$_2$PO$_4$, 0.5% glycerol at pH 7.6) for 2 min. The EDTA-treated culture was then diluted 10:1 into prewarmed medium. The induction was begun 5 min after dilution. The sampling scheme was as in the chloramphenicol experiments except that the samples were held at 37 °C for 30 min after sampling to permit all free message to be completely translated. △, Strain IH82 (Str^R); ○, IH79 (Str^S). The intercepts are not significantly different from each other or the chloramphenicol measured intercepts for IH79 (Fig 1) (into 0.5 ml of actinomycin D 20 µg ml^{-1}). - - -, Lag time for IH79; arrow, lag time for IH82 (Fig. 1).

We isolated a set of streptomycin-resistant mutants (to 200 µg ml^{-1} of streptomycin) which were produced spontaneously from independent cultures. This strain set is therefore, with high confidence, isogenic for all loci but the *strA* locus. Identical procedures for measuring the induction lag revealed a significant increase in the lag time for the streptomycin-resistant derivatives of IH79 over the parent strain (see Fig. 1 in which data for the parent and one such derivative are presented). The independence of the *strA* mutations in this set, the negligible probability of double mutation and the well characterised nature of the *strA* locus as the structural gene for the 30S ribosomal protein S12 and the only mutational locus for the high level streptomycine resistance[11], strongly suggest that the change in speed of protein synthesis is caused by a change in the ribosome speed during translation, rather than by a change in transcription rate.

This conclusion can be tested further by measuring the lag time for the completion of the first messenger RNA (mRNA) transcript of the gene. We have measured this time by using the DNA-binding drug actinomycin-D to stop transcription in a set of samples taken in a time series identical to that described above[12]. The time lag observed by this method (see legend to Fig. 2) is the time required for the passage of the RNA polymerase molecule down the full length of the *z* gene, the time for completion of the initial mRNA. The results (shown in Fig. 2) revealed no significant difference between sensitive and resistant strains and support our presumption that the mutation to streptomycin resistance affects the elongation speed and leaves the transcription speed essentially unchanged.

There is evidence that translation speed and transcription speed are coupled[14] by some yet unknown mechanism. Judging from the results of Gupta and Schlessinger[14] we would expect, however, to see a significant shift in transcription speed only for translation speeds much less than we observe in IH82.

These experiments show clearly that ribosome speed in *E. coli* is not a fixed parameter inherent to the protein synthetic apparatus, but a variable determined by the kinetics of translation and ultimately by the structure of the ribosome. (After this work was completed another, possibly related, phenomenon was reported in which increased levels of streptomycin in streptomycin-dependent strains apparently cause a proportional increase in the speed of translation[14]) We have observed a shift from about 14.7 amino acids per s in the wild type (*Str*^{s}) to about 10.5 amino acids per s in some ribosomal mutants (based on a β-galactosidase length of approximately 1,173 amino acids[15]). Furthermore, the correlations between speed and ribosomal accuracy which are expected from simple kinetic models are in agreement with the observations that mutation to streptomycin resistance but not to spectinomycin resistance (data not shown), which does not affect ribosomal accuracy, increases accuracy and decreases ribosome speed. The nature of the delayed induction curve seen in the streptomycin-resistant strains suggests that the delay is caused by a change in elongation speed and not in the ribosomal initiation rate: a decreased initiation frequency would cause a decreased rate of β-gal synthesis, not just a delay in an otherwise unchanged induction curve as we observe. A more direct separation of the two effects will, however, be necessary before this question can be settled completely.

Further experiments, designed to investigate the accuracy–speed connection suggested by this work, have been carried out on previously characterised *strA* alleles and on a characterised *ram* allele. This work (to be reported elsewhere) indicates that the *ram* allele reverses the effect of mutation to *Str* resistance, and that *strA* alleles may be ordered by their ribosome speeds. Further biochemical and genetic investigations of the kinetics of translation may lead to a fundamental understanding of the molecular processes underlying the discriminatory functions central to the information transfer which occurs at the ribosome during protein synthesis.

This work was carried out under the auspices of the USERDA.

Regulation of ribosomal RNA methylation in a temperature-sensitive mutant of BHK cells

CONSERVATION of methylated sequences of mammalian ribosomal precursor RNA (pre-rRNA) into mature cytoplasmic ribosomes suggests an essential structural or regulatory function for these modified bases[1–3], although the role of post-transcriptional methylation is not clear At the non-permissive temperature (39 °C), *ts 422E*, a temperature-sensitive mutant of BHK 21/13 cells[4–6], is deficient in 28S rRNA maturation and assembly of 60S ribosomal subunits, although transcription of 45S pre-rRNA and cytoplasmic appearance of 18S rRNA and 40S subunits remains unimpaired[3]. To examine the relationship between RNA methylation and the processing of ribosomes, we have studied this mutant and find it contains methyl-deficient pre-rRNA. Our results show an expanded pool of nuclear 45S pre-rRNA molecules in the mutant at 39 °C, suggesting an inhibition of its processing to 32S RNA. In addition, 45S and 32S precursor molecules in *ts 422E* are substantially undermethylated relative to the pre-rRNAs of wild-type BHK cells at 39 °C but identical at the permissive temperature (33 °C). The residual amount of mature

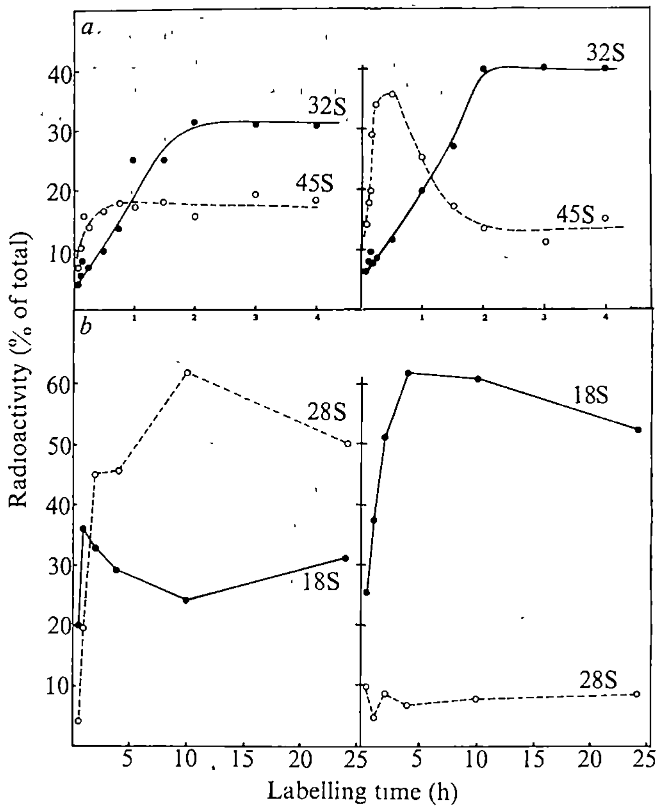

Fig. 1 Accumulation of nuclear (*a*) and cytoplasmic (*b*) ribosomal RNA in *ts 442E* and BHK cells. Monolayer cultures of wild-type BHK (left panels) and *ts 422E* cells (right panels) were shifted from 33 to 39 °C, and after 12 h were labelled with 25 µCi ml^{-1} 5,6-^{3}H-uridine (37.6 Ci mmol^{-1}) in Dulbecco–Vogt Modified Eagle's Medium (DME) supplemented with 3 µM uridine plus 10% calf serum. Collected cells were lysed in 2% citric acid, 0.5% Triton X-100 (Rohm and Haas, Philadelphia) and nuclei were deposited and washed twice with the same buffer by centrifugation at 800*g* for 2 min Nuclear pellets suspended in 10 mM Tris-HCl (*p*H 9.0), 0.2 M NaCl, 10 mM EDTA, 0.5% SDS (NETS buffer) were extruded through a 22 gauge needle to shear DNA then alternately extracted at room temperature with phenol: chloroform. isoamyl alcohol (50:50:1) and chloroform · isoamylalcohol (24:1) until the interfacial layer was clear of denatured protein[18] Post-mitochondrial supernatants prepared from cells lysed as described previously[19] by centrifugation at 10,000 r.p.m. for 10 min in the Sorvall SS-34 rotor, were adjusted to 70 mM $MgCl_2$ for 45 min at 0 °C to precipitate cytoplasmic ribonucleoproteins (RNP)[20]. Ribosomes pelleted by centrifugation at 10,000 r.p m for 10 min were dissolved in NETS buffer, deproteinised, and RNA was precipitated with 2 vol. 95% ethanol. Nuclear RNA samples dissolved in 200 µl NETS buffer were centrifuged in 4 ml linear 15–30% sucrose density gradients in NETS buffer at 23 °C for 90 min at 56,000 r p.m. in a Beckman SW56 rotor. Cytoplasmic RNA dissolved in 1 ml NETS buffer were centrifuged in 36 ml SDS-containing 15–30% sucrose density gradients at 23 °C for 17 h at 23,000 r.p.m in a Beckman SW27 rotor. Radioactivity in 45S, 32S, 28S, 18S RNA were expressed as a percentage of the total acid-insoluble radioactivity in the gradient, including the pellets. In these analyses, 32S and 36S pre-rRNAs were combined since the distribution of these RNA molecules can vary in *ts 422E* cells[21].

28S rRNA that appears in *ts 422E* cytoplasm at 39 °C is markedly methyl deficient.

In a precursor–product relationship, a reduced rate of conversion of intermediate species results in an increased proportion of precursor. If both wild-type and mutant cells are grown at 39 °C, inhibition of 45S processing in *ts 422E* should result in apparent nuclear accumulation of precursor molecules in the temperature-sensitive variants. This prediction was tested in the experiment shown in Fig. 1 where both cell types were labelled with ^{3}H-uridine at the non-permissive temperature and the kinetics of accumulation of nuclear pre-rRNA and cytoplasmic rRNA were followed.

The cells were labelled in growth medium supplemented with unlabelled uridine to ensure that the specific activity of the UTP pool would be constant throughout the period of incorporation (unpublished data). In BHK cells, 45S and 32S pre-rRNAs and 28S and 18S rRNAs exhibited accumulation patterns consistent with their known precursor–product relationship[7,8] (Fig. 1). Accumulation of 45S pre-rRNA in the mutant was, however, aberrant. During the first 30 min of labelling, the content of nuclear 45S RNA in *ts 422E* was 30–35% of the total labelled RNA compared with a maximum of only 15–20% in BHK cells in similar conditions (Fig. 1). As stable nuclear and nucleolar RNAs accumulated, the fraction of radioactivity in 45S pre-rRNA decreased until by 2–3 h the relative amount of pre-rRNA was the same in the mutant and wild-type cells. The kinetics of mature cytoplasmic 18S and 28S rRNA accumulation in the mutant showed, as before[5], a marked inhibition of new 28S rRNA appearance at 39 °C. The early increase in nuclear 45S pre-rRNA content in the mutant indicated an expansion of the nucleolar pool of 45S pre-rRNA, suggesting that the transcript was deficient in some essential aspect.

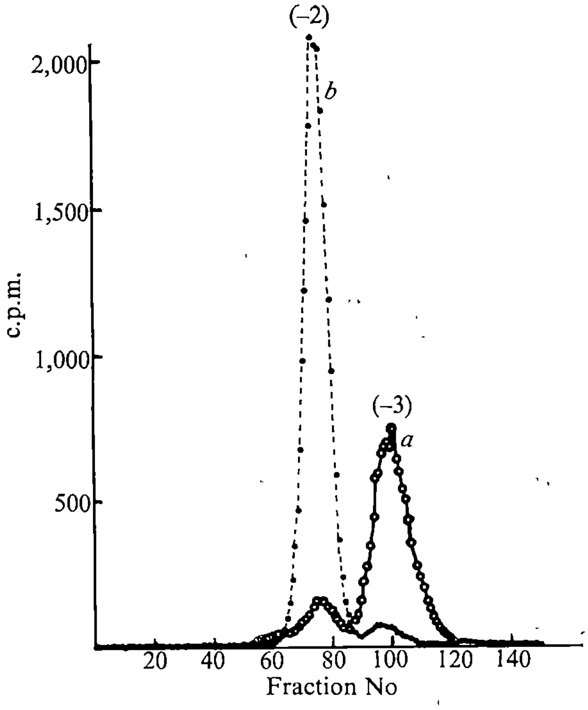

Fig. 2 Separation of mononucleotides and dinucleotides by DEAE–Sephadex chromatography. BHK cells were labelled for 3.5 h with (*a*) 20 μCi ml^{-1} L-methyl-^{3}H-methionine (6.3 Ci mmol^{-1}) and (*b*) 0.1 μCi ml^{-1} ^{14}C-uridine (57 mCi mmol^{-1}) in DME containing 20 μM methionine, 4 μM uridine, 20 mM sodium formate, and 20 μM guanosine to suppress non-methyl purine ring labelling[12] beginning 16 h after shift up to 39 °C. Ribosomal RNA prepared from $MgCl_2$-precipitated cytoplasmic RNP was sedimented at 23 °C in a 36 ml SDS-containing 15–30% sucrose gradient for 17 h at 23,000 r.p.m in an SW27 rotor. 18S rRNA was precipitated from the gradient with 2 vol 95% ethanol, dissolved in 2 ml 0.3 N KOH, and hydrolysed for 18 h at 37 °C. The alkaline hydrolysate was neutralised with ice-cold 0.3 N perchloric acid, chilled at 0 °C for 10 min, and centrifuged at 5,000 r.p.m. for 5 min to remove precipitated potassium perchlorate. The neutralised sample was applied to a column of DEAE–Sephadex (19 × 1.2 cm; A-25, Pharmacia Fine Chemicals, Piscataway, New Jersey), washed into the column with 25 ml 20 mM Tris-HCl (*p*H 7.4), 7 M urea, 0.1 M NaCl, and eluted with a linear 100 ml gradient of 0.1–0.4 M NaCl in 20 mM Tris-HCl (*p*H 7.4), and 7 M urea[10,22]. After completion of the gradient, the column was washed with 40 ml 0.4 M NaCl, 20 mM Tris-HCl (*p*H 7.4), and 7 M urea. Fractions were assayed for radioactivity by counting in a gel of 2.0 ml H_2O plus 10 ml scintillation fluid containing 2 parts xylene, 1 part Triton X-100 and 8 g Omnifluor (New England Nuclear, Boston, Massachusetts) per litre.

Because methylation of 45S pre-rRNA is an apparent requirement for completion of ribosome maturation[1,9], we compared the extent of 45S methylation in the wild-type and mutant cells. Ninety-five per cent of methylations found in HeLa cell 45S pre-rRNA are modifications of the 2′-OH ribose moiety of the nucleoside[1]. Since this modification protects the phosphodiester linkage between the 3′-hydroxyl of that nucleotide and the 5′-hydroxyl of the neighbouring nucleotide from alkaline hydrolysis, separation of mononucleotides from dinucleotides on anion exchange columns[10] after alkaline hydrolysis provides an estimate of rRNA methylation (Fig. 2). As shown in Fig. 2, approximately 96% of the uridine incorporated into 18S rRNA is found in the mononucleotide fraction, but methyl label is preferentially incorporated into the dinucleotides. This pattern demonstrates the general labelling characteristics of ^{3}H-uridine and the relative specificity of methyl-^{3}H-methionine for incorporation into 2′-hydroxyl ribose residues.

The relative methylation of pre-rRNA in BHK and *ts 422E* cell lines was examined initially by pulse labelling at 39 °C with methyl-^{3}H-methionine and ^{14}C-uridine (Table 1). The ratio of ^{3}H-methyl/^{14}C-uridine radioactivity was used as an index of the extent of methylation. By this criterion, 45S pre-rRNA from the mutant is approximately 50% undermethylated, and the 32S RNA has only a third of the methyl content of wild-type 32S RNA at the non-permissive temperature. Since 28S rRNA in mammalian cells is derived from the 32S molecule[11,12], undermethylation of 28S sequences would result in 32S RNA exhibiting a lower degree of methylation than complete 45S molecules which also contain properly methylated 18S RNA sequences (Table 1).

The apparent undermethylation observed in *ts 422E* at 39 °C could also be explained by decreased uptake of methionine relative to uridine. Therefore, we estimated ribose methylation of precursor and mature ribosomal RNA in BHK and *ts 422E* cells by measuring radioactivity in alkali-resistant dinucleotides of uridine-labelled cells. Although this approach measured only 2′-*O*-methylribose in or adjacent to uridine and/or cytidine, difficulties resulting from possible pool and transport differences were eliminated. The extent of undermethylation would seem less by

Table 1 Relative extents of methylation at 39 °C in BHK and *ts 422E* pre-rRNA

RNA	Radioactivity (c.p.m.) ^{3}H-methyl	^{14}C-uridine	^{3}H-methyl/ ^{14}C-uridine
BHK 45S	2,230	8,034	0.28
422E 45S	3,407	21,689	0.16
BHK 32S	5,115	28,611	0.18
422E 32S	5,717	98,716	0.06

BHK and *ts 422E* cells were labelled 45 min with 25 μCi ml^{-1} L-methyl-^{3}H-methionine and 0.1 μCi ml^{-1} ^{14}C-uridine as in Fig. 2, beginning 18 h after shifting to 39 °C. Nucleoli prepared as described by Penman[23] were deproteinised (Fig. 1) and nucleolar RNA was centrifuged in 36 ml linear 15–30% sucrose density gradients in NETS at 20,000 r.p.m. for 16 h at 23 °C in an SW27 rotor. Aliquots (50 μl) of gradient fractions were assayed for acid-insoluble radioactivity. Nominal 45S RNA and 32S RNA peak fractions were precipitated with ethanol, and chromatographed on DEAE–Sephadex after alkaline hydrolysis as in Fig. 2. Values represent total combined radioactivity in the mononucleotide and dinucleotide peaks. ●

Table 2 Estimation of 2′-*O*-methyl ribose in uridine-labelled ribosomal pre-rRNA

	Radioactivity					
	Mononucleotides (−2) (c.p.m. × 10^{-4})		Dinucleotides (−3) (c.p.m. × 10^{-3})		Total radioactivity in dinucleotides (%)	
	33 °C	39 °C	33 °C	39 °C	33 °C	39 °C
Experiment 1						
BHK 45S	–	60.0	–	8.3	–	1.36
422E 45S	–	53.3	–	4.8	–	0.89
Experiment 2						
BHK 45S + 32S	75.6	105.1	18.1	24.7	2.33	2.34
422E 45S + 32S	252.8	57.9	56.9	11.9	2.20	1.75
BHK 28S	82.1	70.7	23.1	19.5	2.73	2.69
422E 28S	112.0	7.7	31.3	1.0	2.55	1.32
BHK 18S	67.6	25.5	25.3	11.9	3.60	4.47
422E 18S	115.1	38.2	57.0	17.1	4.70	4.30

In experiment 1, BHK and *ts 422E* cells were pulse labelled in DME with 100 μCi ml^{-1} ^{3}H-uridine beginning 22 h after shift-up to 39 °C. 45S pre-rRNA prepared by sucrose density gradient sedimentation of nucleolar RNA was hydrolysed with 0.3 N KOH at 37 °C and chromatographed on DEAE–Sephadex (Table 1). In experiment 2, wild-type and mutant cells were labelled 3.5 h with 5 μCi ml^{-1} ^{14}C-uridine at 33 °C. 45S and 32S nucleolar RNA was prepared and analysed as described above. $MgCl_2$-precipitated cytoplasmic RNP was deproteinised and RNA was sedimented in sucrose density gradients as in Fig. 1, and the major fractions under the separated 28S and 18S rRNA peaks were pooled and precipitated with 2 vol 95% ethanol. Contaminating poly(A)-containing mRNA was removed by oligo(dT)-cellulose chromatography[25]. Purified rRNAs hydrolysed with KOH were chromatographed on DEAE–Sephadex. Details of experiment 3 are the same as for experiment 2, except that wild-type and mutant cells were labelled beginning 19 h after shift-up to 39 °C. Three replicate samples of uridine-labelled HeLa cell rRNA were hydrolysed and chromatographed on DEAE–Sephadex to test the reproducibility of the technique. For these replicates the mean fraction of ^{3}H-uridine in the dinucleotide region was 2.83% with a standard deviation of 0.096 or 3.4% of the mean value.

this assay, because these experiments only scored for uridine label in dinucleotides against mononucleotides.

The results of DEAE–Sephadex chromatography of alkali-hydrolysed RNA from cells labelled for 30 min or 3.5 h with uridine (Table 2) confirmed the previously observed undermethylation of *ts 422E* nucleolar and 28S cytoplasmic rRNA. With the exception of 18S rRNA which yielded less reproducible values than other species of RNA, the differences between mutant and wild-type cells seen at the permissive temperature can be attributed to variation in the method (see legend to Table 2), but the differences observed at 39 °C must reflect the conditional lethal phenotype. The similarity of RNA methylation in the wild-type cells at 33 and 39 °C is a further indication of the accuracy of this analysis (Table 2).

Methylation of rRNA is of two types: 2′-*O*-ribose modification and methylation of specific sites in the purine and pyrimidine rings. In HeLa cells, 80–90% of methyl derivatives in rRNA are modifications of the 2-OH-ribose moiety[1,13,14]. The experiments presented above clearly show deficient methylation of 2′-*O*-ribose moieties in 28S rRNA and its precursors in *ts 422E* cells grown and labelled at 39 °C. Since phosphodiester bonds adjacent to base methyl derivatives may also be resistant to alkaline hydrolysis[15], however, the observed differences may not be due exclusively to alterations in 2′-*O*-methylation.

Physical studies have shown that methylation of ribose residues can alter the conformation of single-stranded RNA molecules[16] Although the details of eukaryotic ribosome maturation are not known, it is likely that processing of 28S rRNA requires the sequential association of specific proteins and 32S RNA to give rise to the nucleolar 55S pre-ribosomal particles. Inadequate methylation of the 28S segment could alter the conformation of the ribosomal precursors, preventing the normal association of processing enzymes and thus inhibiting the appearance of 28S RNA in the cytoplasm. Assuming 18S RNA sequences at the 5′ end of the transcript[17] are properly methylated, and that methylation and transcription are closely coupled, it is possible that the distal portions of the transcript containing 28S sequences are inhibited from being adequately modified. Alternatively, a precursor-associated protein may be the primary target of the temperature-sensitive lesion, placing the transcript in a conformation within the precursor particle that is unfavourable for completion of adequate methylation.

After submission of this paper, Toniolo and Basilico reported increased accumulation of nucleolar pre-rRNA in *ts 422E* at 39 °C compared with wild-type cells, but these authors did not detect differences in extent of pre-rRNA methylation[25]. Our assay for rRNA methylation may have been more specific, however, since we labelled with methionine in conditions which suppressed non-methyl purine ring labelling (see legend to Fig. 2).

This work was supported by grants from the NIH. A.K. is a recipient of a Cancer Research Scholar Award from the American Cancer Society, Massachusetts Division; A.J.O. is a Research Fellow of the Medical Foundation Inc., Boston, Massachusetts. The wild-type and mutant cell lines were generously supplied by Dr C. Basilico. We thank Ms R. Huffman and D. Frederick for valuable assistance and Dr R. A. Malt for encouragement and extensive use of his facilities.

Restriction of template capacity of rat liver chromatin by a non-histone peptide from calf thymus

We have reported[1] the isolation of a thymic peptide which strongly inhibits DNA-directed RNA polymerase *in vitro*. We have shown that transcription is controlled at the level of initiation. The active factor was isolated from aqueous ultrafiltered thymus extracts, purified by chromatography, first on DEAE–cellulose and then on Dowex 50 WX2, and characterised as a peptide of low molecular weight (<5,000). Its biological activity cannot be attributed to the presence of a nuclease or of a histone fragment. The inhibition of RNA synthesis is due to an ionic interaction between the peptide and DNA. The physicochemical and thermodynamic properties of this interaction are described elsewhere[2]. We report here the effect(s) of the thymic peptide on transcription of rat liver chromatin With some obvious limitations[3], the *in vitro* chromatin transcription system is closer to the *in vivo* state than the purified DNA. Our experiments were prompted by our previous results, which demonstrated that the thymic extract modifies the physicochemical state of DNA and the interactions between DNA and nuclear proteins in the liver of old rats[4,5].

The purified thymic fraction, designated fraction 1_6 (see legend to Fig. 1), strongly inhibited chromatin transcription by *Escherichia coli* RNA polymerase (Fig 1). This effect was proportional to the concentration of factor up to 70% inhibition. Contrary to our data on inhibition of DNA transcription[1], even when doses of the factor larger than shown in Fig. 1 were added, chromatin transcription was never completely stopped, indicating that the thymic factor affected only part of the RNA synthetic pathways. Since the thymic factor acts on initiation of transcription rather than on elongation[1], it is possible that the peptide cannot inhibit chromatin transcription by endogenous RNA polymerases, which are probably linked to the chromatin itself. We therefore tested for chromatin-directed RNA synthesis *in vitro* without added *E. coli* polymerase, in both the presence and absence of the thymic extract. Figure 2*a* shows that, in the absence of exogenous RNA polymerase, chromatin transcription constituted only 10–15% of total transcription observed in the presence of exogenous RNA polymerase from *E. coli* In these conditions the thymic factor was ineffective. These data support the hypothesis that the thymic factor exerts its activity on initiation.

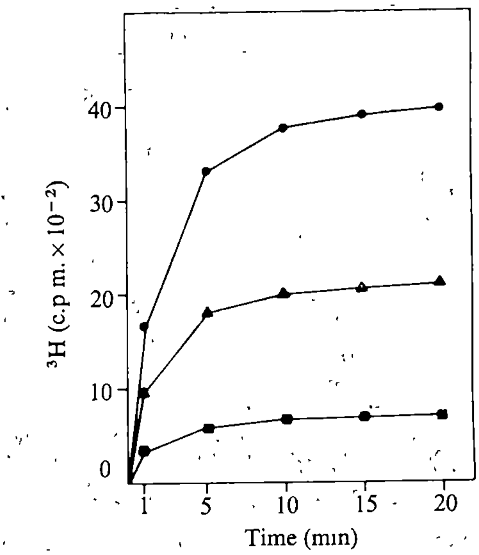

Fig. 1 Time course of RNA synthesis directed by rat liver chromatin: incorporation of ^{3}H-CMP. 0 75 ml of the complete incubation mixture for RNA synthesis contained: 30 μmol Tris buffer (*p*H 7.5), 3 μmol $MgCl_2$, 0.75 μmol $MnCl_2$, 9 μmol β-mercaptoethanol, 0.3 μmol each of ATP, GTP, CTP and UTP, 2 nmol ^{3}H-CTP (22 Ci, nmol^{-1}, Radiochemical Centre, Amersham), 4 U RNA polymerase from *E. coli* and 10 μg chromatin DNA. 0.1 or 0.2 ml of the purified thymic fraction corresponding respectively to 4 μg and 8 μg protein was added to the incubation mixture; in the controls the extract was replaced by 0.1–0.2 ml saline. Incubation for RNA synthesis was carried out in 10-ml Erlenmeyer flasks at 37 °C, 75 shakes per min. Determinations of the radioactivity incorporated into the acid-insoluble fraction of RNA, the preparation of the thymus extracts and the purification of the active factor, designated fraction 1_6, were carried out as before[1]. Fraction 1_6 consisted of peptide(s) of low molecular weight: thin layer high voltage electrophoresis showed four ninhydrin-positive bands. As far as the affinity binding between DNA and thymus factor is concerned, evidence presented elsewhere[2] indicates that when DNA at 1 mg ml^{-1} is incubated with a fraction 1_6 (100 μg ml^{-1}), about 20 μg protein binds to DNA. This is taken as evidence that fraction 1_6 is mostly composed of active thymic factor. Total chromatin was extracted from livers of 12-month-old Sprague–Dawley rats according to the modified method of Bostock and Prescott[12]: nuclei were not broken by sonication but by homogenisation twice in Potter Helvehyem after rapid freezing and thawing. We modified Bostock and Prescott's method to obtain the chromatin in the most native state possible. The RNA polymerase from *E coli* was purified as described before[13]. The data in the experiments described are the average of experiments made in duplicate, the values of which have never shown variations above 10%. ●, Control; ▲, fraction 1_6:5 μg protein per ml (final concentration); ■, 10 μg protein per ml (final concentration).

Table 1 Template capacity of calf thymus DNA and of rat liver heterochromatin and euchromatin

Reaction mixture		^{3}H-CMP incorporation (c.p.m. mean ± s.e.m.) Control	Thymus factor added	% Inhibition
Calf thymus DNA	+ *E. coli* RNA polymerase	22,015±810	1,601±245	93
Calf thymus DNA	+ calf thymus RNA polymerase	20,242±640	1,721±315	91
Rat liver heterochromatin	+ *E. coli* RNA polymerase	2,570±180	960±105	63
Rat liver euchromatin	+ *E. coli* RNA polymerase	4,015±215	1,120±148	72
Rat liver heterochromatin	+ calf thymus RNA polymerase	1,137±110	653±80	42
Rat liver euchromatin	+ calf thymus RNA polymerase	1,701±98	855±60	49
Rat liver heterochromatin	+ rat liver RNA polymerase	1,580±124	615±132	61
Rat liver euchromatin	+ rat liver RNA polymerase	2,424±170	715±97	70

Incorporation of ^{3}H-CMP by means of RNA polymerase from *E. coli*, calf thymus or rat liver, in both the presence and absence of the thymic factor (final concentration 10 μg protein per ml), after 30 min of incubation. The preparation of thymus extract, the incubation mixture and other conditions for RNA synthesis were as in the legend to Fig. 1. RNA polymerase from *E. coli* was purified as described by Hurwitz[13] and the RNA polymerases II from calf thymus and rat liver as described by Stein and Hausen[14]. The extraction of the chromatin from rat liver and the fractionation of the total chromatin in heterochromatin and euchromatin were carried out according to the modified method (see legend to Fig. 1) of Bostock and Prescott[12] In some experiments the fractionation of the total chromatin in heterochromatin and euchromatin was carried out by means of gel filtration on BioGel A-50 (BioRad) as described by Janowski *et al.*[15]. The determinations of the buoyant density and of the DNA, RNA and protein contents of hetero- and euchromatin were effected by means of the determination of the refraction index[16] and of diphenylamine, orcinol and Lowry reactions respectively:

	Buoyant density	DNA	RNA	Protein
Heterochromatin	1.711	1	0.160	2.071
Euchromatin	1.699	1	0.175	1.714

To confirm this hypothesis, chromatin was preincubated for 1 min in the presence of *E. coli* RNA polymerase and UTP, GTP and ATP nucleotides. At time zero the reaction mixture was made 0.4 M in ammonium sulphate, the thymic fraction or saline was added and the propagation reaction was started by adding CTP and ^{3}H-CTP. During preincubation polymerase binds to chromatin and initiates transcription, but propagation is blocked by the absence of CTP: when CTP is added propagation proceeds, but the presence of high concentrations of ammonium sulphate precludes further initiation or reinitiation[6,7]. Figure 2*b* shows that in these conditions the thymic factor did not affect RNA synthesis and therefore inhibited the initiation reaction of transcription. Later we investigated the action of the thymic factor on transcription in different states of chromatin condensation: that is heterochromatin and euchromatin, the characteristics of which are given in the legend to Table 1. The transcription of heterochromatin and euchromatin, in both the absence and presence of thymic factor, was tested by adding various RNA polymerases: different specificities of chromatin transcription by RNA polymerase from prokaryotic or eukaryotic cells have been reported[8,9]. RNA polymerases from *E. coli* and RNA polymerases II from rat liver and calf thymus were used. Table 1 shows that the thymic peptide inhibited transcription of heterochromatin and euchromatin by polymerases from both prokaryotic and eukaryotic cells, regardless of the organ of origin of eukaryotic polymerases.

The data presented here provide evidence for our hypothesis that the thymic peptide is responsible for regulation at the level of transcription. The addition of the factor restricts the distribution of available sites for the initiation of transcription on the chromatin. These observations suggest that the factor regulates transcriptional capacity, which may be related to cell differentiation. This is supported by our finding that the thymic factor was not extracted from differentiated tissues such as kidney, whereas it was particularly abundant in bull spermatozoa (unpublished results). The inhibition of chromatin transcription by this factor extracted from spermatozoa may explain our previous data[10] showing that extracts of spermatozoa inhibit differentiation of seminiferous tubule cells of testicles from young rabbits.

The data presented here are in good agreement with the demonstration[11] that chromatin from several mammalian species contains non-histone protein fractions including specific negative regulatory factors ionically linked to DNA.

Fig. 2 Time course of RNA synthesis directed by rat liver chromatin: incorporation of ^{3}H-CMP. *a*, In the absence of exogenous *E. coli* RNA polymerase in the incubation mixture. Other ingredients for RNA synthesis were as given in the legend to Fig. 1. ●, Control; ■, thymic fraction 1_6 (final concentration 10 μg protein per ml). *b*, The chromatin was preincubated for 1 min in the presence of *E. coli* RNA polymerase and ATP, GTP and UTP. At time zero the reaction mixture was made 0.4 M in ammonium sulphate, thymic factor or saline was added and the propagation reaction was started by adding CTP and ^{3}H-CTP. Incubation mixture and other conditions for RNA synthesis were as given in the legend to Fig. 1. ●, Control; ■, fraction 1_6 (final concentration 10 μg protein per ml).

Independence of plasmid incompatibility and replication control functions in *Staphylococcus aureus*

THERE are two basic requirements for the stable maintenance of an autonomous plasmid replicon, namely replication at a constant rate with respect to the cell division cycle and distribution of replicas to daughter cells.

The precise nature of the genetic functions involved in satisfying these two requirements has yet to be ascertained; but it is probable that in general, both plasmid-linked and host chromosome-linked genetic determinants are involved. Of the former there are two well defined functional classes: (1) genes involved directly in replication[1–3] and its control, including the origin, and (2) genes involved in the determination of plasmid incompatibility specificity[4–6]. No genes known to affect distribution of plasmid replicas have been identified.

Incompatibility, the inability of closely related plasmids to be stably co-maintained[7], has been found for the penicillinase plasmids of *S. aureus* to be determined by a genetic locus, *inc*, that has not been separable by recombination from *repA*, a gene encoding a diffusible product required for autonomous replication[1,4]. Together, these two genetic functions plus the origin define a local region of the plasmid that is both necessary and sufficient for autonomy, the *mcr* region[4]. Similar localisation of autonomy functions has been observed for plasmids of enteric organisms[8].

Because the replication of a plasmid entering a cell carrying another with which it is incompatible is temporarily or, possibly in some cases permanently, inhibited[9–11], it has been

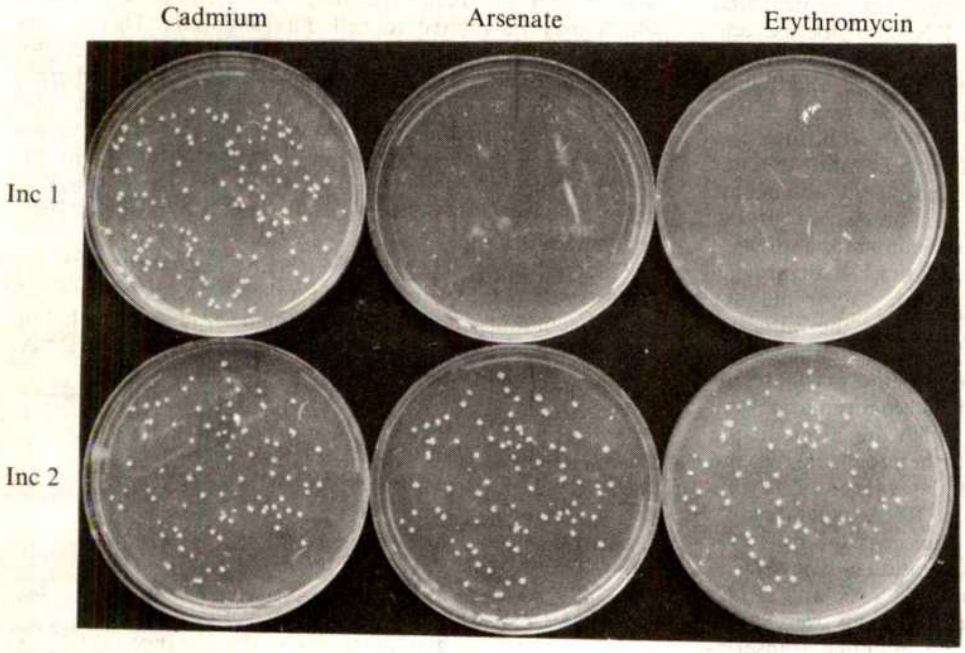

Fig. 1 Incompatibility between integrated and autonomous plasmids. Cultures of RN2428 (upper part of photograph) and RN2429 were diluted and plated on non-selective medium and incubated at 43 °C. The resulting colonies were replica-plated to three different selective media: GL-cadmium agar (selective for the integrated plasmid, pRN3091); GL-arsenate; and GL-erythromycin (selective for the autonomous plasmid, pRN3025 and pRN4031). The replicas were photographed after 18 h of incubation at 32 °C.

assumed that the incompatibility determinant is involved in replication control, for example, it may encode a specific repressor of replication[12].

In this report we present evidence suggesting that in the *S. aureus* system, the plasmid *inc* and *repA* determinants are genetically as well as functionally distinct and that the *inc* locus is not involved in replication or its control but instead may be involved in the distribution of replicas.

Two different chromosomally integrated derivatives of an incompatibility type 1 (Inc1) *S. aureus* penicillinase plasmid, pI258, were studied. One of these, pRN3150, is incompatibility-defective, yet expresses the *repA* function[1]; the other, pRN3091, is *repA*$^-$ (thermosensitive for replication) yet expresses incompatibility at the restrictive as well as at the permissive temperature. Strains carrying the *repA*$^+$ *inc*$^-$ pRN3150 were able to maintain stably and complement for replication seven different superinfecting *repA*$^-$ Inc1 plasmids[1]. But a recombinant derivative, pRN3151, in which the *repA36* allele had been substituted for the *repA*$^+$, was unable to complement for replication any of the seven *rep*$^-$ mutants (unpublished data); thus, there is evidence for only one plasmid-linked *rep* cistron.

The converse test, namely whether a *repA*$^-$ mutant can express incompatibility or not was also performed with an integrated plasmid (in this case the Rep$^-$(Ts) pRN3091[13]) since there is no simple way to test an *autonomous* Rep$^-$(Ts) plasmid for the expression of incompatibility at the restrictive temperature. Transductional superinfection of strain RN1979 (carrying the integrated pRN3091) with plasmids pRN3025 (Inc1) and pRN4031 (Inc2) was accomplished by selection for erythromycin resistance[14]. Eight transductants from each cross were examined and the following results were obtained: as expected, the Inc2 plasmid, pRN4031, was always maintained stably without selection. The Inc1 plasmid, pRN3025, could also be maintained but only by continued selection for erythromycin or arsenate resistance. Organisms grown on arsenate-containing medium, selective for the donor plasmid, were diluted and plated on non-selective medium (GL agar[8]) and allowed to form colonies at 32 °C and at 43 °C (the restrictive temperature for the Rep$^-$(Ts) mutation). These were then replicated separately to plates containing cadmium, arsenate, or erythromycin. As shown in Fig. 1, colonies of RN2428 (RN1979 superinfected with the *inc1* plasmid, pRN3025) lost arsenate and erythromycin resistance during growth at 43 °C on non-selective medium, whereas colonies of

* Gene abbreviations and other nomenclature are as recommended by Novick *et al.*[7].
† The host bacterium is strain 8325–4, except for RN1974 in which the host is strain 147 (ref. 14).

RN2429 did not. Similar results were obtained for colonies of these two strains grown at 32 °C. These results are interpreted as the expression of incompatibility by the intergrated *repA*$^-$ plasmid at both permissive and restrictive temperatures, demonstrating the independence of the *inc* and *repA* determinants.

To verify the inference that loss of arsenate and erythromycin resistance is an indication of loss of the entire plasmid, thirty colonies of strain RN2428 that had been grown on non-selective medium were scored by disk sensitivity tests and by the PNCB stain for penicillinase activity[14]. There were scorable allelic differences at four plasmid loci —*bla, asa, cad*, and *erm*; on subculture, twenty-eight of the colonies showed the same resistance pattern as the resident plasmid and a penicillinase stain pattern indicative of homozygosity for the integrated *bla* locus. Two colonies showed stable patterns suggestive of recombination between the integrated and autonomous plasmids.

Although it seemed likely on the basis of the foregoing results that the superinfecting penicillinase plasmid could replicate in the autonomous state, it seemed important to attempt to demonstrate this replication directly and to assess it quantitatively. Accordingly, a dye-buoyant density gradient analysis of plasmid replication was done[1], and the results shown in Fig. 2 were obtained. Incorporation of thymidine into circular duplex plasmid DNA by the incompatible heterozygote, RN2428 (Fig. 2*a*) was nearly as extensive as that by the compatible heterozygote RN2429 (Fig. 2*b*), by comparison with strains carrying the autonomous plasmid alone in each case. As this result could have been due to the presence of unsuspected recombinants, the cultures were tested at the end of the labelling period for the proportion of organisms that would still lose the superinfecting plasmid during incubation on non-selective media. Accordingly, a replica-plating test similar to that shown in Fig. 1 was performed and showed that approximately 80% of the oragnisms in the RN2428 culture were still arsenate-resistant and that at least 95% of these lost resistance on incubation on non-selective medium. On the other hand, 95% of the organisms in the RN2429 culture were arsenate-resistant and of these, less than 1% lost arsenate resistance during incubation on non-selective medium.

It is possible that the somewhat reduced incorporation into plasmid DNA in strain RN2428 (see Fig. 2*a*) was due to a reduction in the number of autonomous copies of the plasmid, normally 8 to 12 per cell[15], in that strain. Experiments are in progress to test this possibility.

We conclude from these experiments that the known plasmid loci affecting incompatibility and replication seem to be genetically separate and functionally distinct in *S. aureus* and that in this system, the expression of incompatibility does not involve inhibition of replication.

Consistent with this conclusion is the fact that it is generally possible, both in *S. aureus* and in *E. coli*, to construct strains carrying pairs of incompatible autonomous plasmids. In such heterozygotes, which can be maintained only by double selection, the two incompatible plasmids replicate side-by-side, and segregate at a measurable, constant rate on nonselective media[9,16,17]. We should like to propose, therefore, a model in which incompatibility between autonomous plasmids is an automatic consequence of the partition process. This model would apply to plasmids with random partition as well as to those with equipartition. Our primary formulation is, however, for the latter since equipartition is evidently a property of staphylococcal plasmids[1].

(1) Copies of a given plasmid are partitioned at cell division by transient attachment to a "partition structure" (the membrane?—compare Jacob *et al.*[2]).

(2) The partition and replication control mechanisms are incompatibility-type specific; that is, they cannot distinguish among plasmids belonging to the same incompatibility set (but they can distinguish among members of different sets).

(3) Plasmids belonging to the same incompatibility set are randomised between cell divisions so that there is a high probability that gross disproportion will develop among them during cell division.

(4) Any disproportion generated during division is likely to be maintained by replication during the next interdivision period; such disproportions will then be amplified during subsequent divisions until subclones containing only one of the pair are generated.

Note that the behaviour of homogenic incompatible plasmids illuminates a feature of equipartition that would otherwise remain obscure, namely randomisation of the plasmid copy pool. The crux of the model is that disproportions generated by this randomisation cannot be corrected because their existence cannot be recognised. The model makes a number of predictions that are readily testable: (1) the segregation behaviour of homogenic

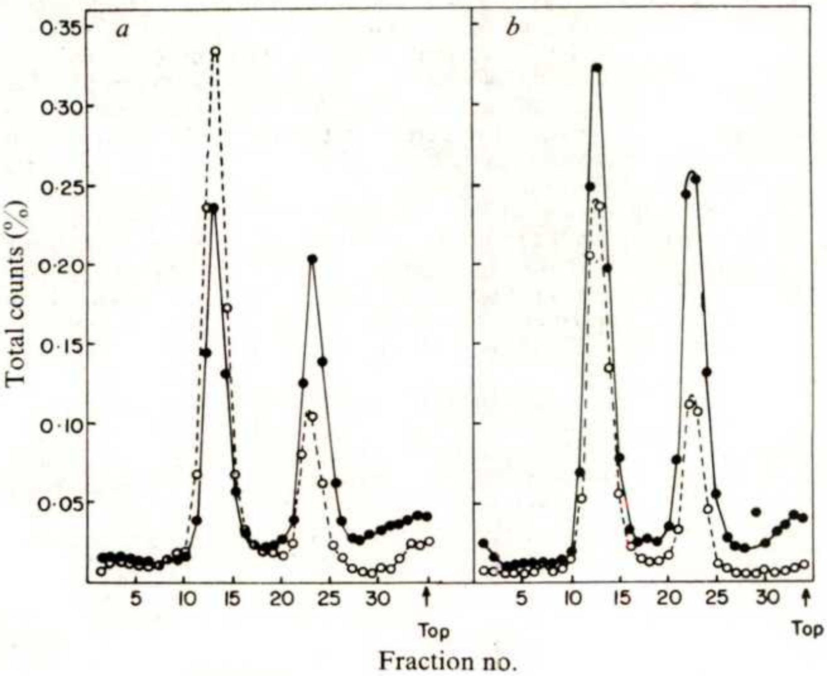

Fig. 2 Replication of incompatible plasmids. *a*. A cleared lysate[19] of a ^{3}H-labelled RN2428 culture mixed with a ^{14}C-labelled RN557 culture was centrifuged to equliibrium in an ethidium bromide–caesium chloride gradient which was fractionated and counted by standard procedures. Counts were mormalised to total incorporatio into the respective cultures. *b*. Dye-buoyant density gradient pattern for lysate of a mixture of a ^{3}H-labelled RN2429 cultures and ^{14}C-labelled RN325. For both, dashed curve, ^{14}C; solid curve, ^{3}H. Density increases from right to left.

incompatible plasmid heterozygotes is solely a function of copy numbers and can be predicted by simple combinatorial analysis; (2) the incompatibility locus is a recognition site for partition and so does not encode a protein—thus it may be regarded as a prokaryotic centromere analogue; (3) a (membrane) protein exists that recognises and binds to this site—such a protein could either be plasmid- or host-coded; (4) the incompatibility locus is not essential for autonomous replication; (5) plasmids with absent or defective *inc* loci will be partitioned randomly in the absence of other plasmids; (6) paradoxically, Inc$^-$ plasmids will not be compatible with Inc$^+$ plasmids of the same original class.

It should be pointed out that this model as stated deals with the hereditary consequences of only one of several possible combinations of replication and partition specificities. For example, it is implict in prediction 6 (above) that equipartition is not a prerequisite for incompatibility; so long as the replication system cannot distinguish between plasmids, the inevitable disproportions arising during cell division will not be correctable and the result will be segregation. In such cases, the incompatibility locus will not be a centromere analogue but rather will correspond to the determinant(s) of replicon recognition specificity.

It should also be mentioned that there are two known situations in which the presence of one plasmid evidently inhibits the replication of another with which it is incompatible. These two situations are (1) delayed replication of an entering plasmid[9,11] and (2) inhibition by a cointegrate replicon of the replication of an autonomous plasmid incompatible with the subsidiary component of the cointegrate. Two examples of the latter are, Hfr strains superinfected by F plasmids[10] and a colE1-pSC101 cointegrate superinfected by pSC101[17]). All of these situations may be manifestations of a copy number control mechanism. In case (1) above, the resident plasmid is present at its full complement of copies and so an entering one is disadvantaged for that reason. Eventually, however, the entering plasmid is able to establish and replicate. In case (2) involving cointegrates, if the number of copies of the subsidiary replicon (for example, integrated F or pSC101) is maintained automatically at a level equal to or greater than its normal autonomous multiplicity, one would expect replication of autonomous copies of the corresponding plasmid to be inhibited and the establishment of that plasmid to be prevented.

The above considerations suggest that as many as three different kinds of genetic mechanism, each operative under a particular set of conditions, may be mainfested as plasmid incompatibility. These are (1) a recognition site for equipartition, (2) a recognition site for replication specificity, and (3) a copy number control mechanism.

The basis of the expression of incompatibility by the integrated *S. aureus* plasmid described here is not intuitively obvious from these considerations. It is unlikely that copy control is involved, since the autonomous plasmid (when alone) is normally present at 8–12 copies per cell[15] and the integrated one at 2–4[18]. Presumably, therefore, the integrated plasmid somehow causes random partition of the autonomous one and prevents correction of the deficiencies in the copy number of the latter that consequently arise during division. Experimental analysis of this possibility is in progress.

Low angle X-ray diffraction patterns of squid retina

THE structure of photoreceptor membranes in the rod outer segments of vertebrates has been studied using X-ray diffraction[1–3], and electron density profiles of the disk membrane at a resolution of 14 Å have been obtained[4]. The ultrastructure of invertebrate rhabdomeric visual cells have been studied using electron microscopy[5] and birefringence[6], but not X-ray methods. We report here low angle X-ray diffraction patterns recorded from squid retina after fixation in glutaraldehyde.

In the squid the rhabdomere structures of the retinula cells[7] are contained within the distal segments[8] (by analogy with the retinal rod outer segments of vertebrates). Electron micrographs[7,8] of the distal segments of squid show an array of microvilli and show that the long axes of the microvilli are perpendicular to the light direction. A single microvillus[7,8] is shown as a thin hollow cylinder about 1–2 µm long and about 700–1,000 Å in diameter. The microvilli appear to be in regular hexagonal arrays. A three-dimensional reconstruction of the squid distal segment[7] shows that the adjacent hexagonal arrays of different retinula cells are approximately perpendicular to each other. The squid retina is well suited to X-ray study because the volume fraction of the microvilli in the squid retina is large when compared with other invertebrates. The distal segments are rather long, about 300 µm, and the distal segments of squid[7] like those of octopus[9] are closely packed together.

Fresh squids were obtained at Marine Biological Laboratory, Woods Hole. After dissection the squid eyes were immediately fixed in 6% glutaraldehyde in Tris buffer (*p*H 7.0) and stored in a refrigerator at about 4 °C. In the X-ray experiment a 1-mm strip was cut from the fixed eye and mounted in a specimen chamber. The X-ray procedures for recording diffraction from squid retina were very similar to those used in obtaining X-ray patterns from vertebrate retina[1–3]. Low angle X-ray diffraction patterns were taken with the X-ray beam incident parallel to the retina surface, and incident perpendicular to the light direction and to the long axis of each distal segment. Exposure times varied from 1 h to 1 d using an Elliott rotating anode microfocus X-ray generator and an optically focusing X-ray camera[10].

Initially, slit collimation was used to explore whether low angle X-ray diffraction could be recorded from our X-ray specimens of squid retina. A series of diffraction orders from a lamellar repeating distance of $d = 620 \pm 10$ Å along the light

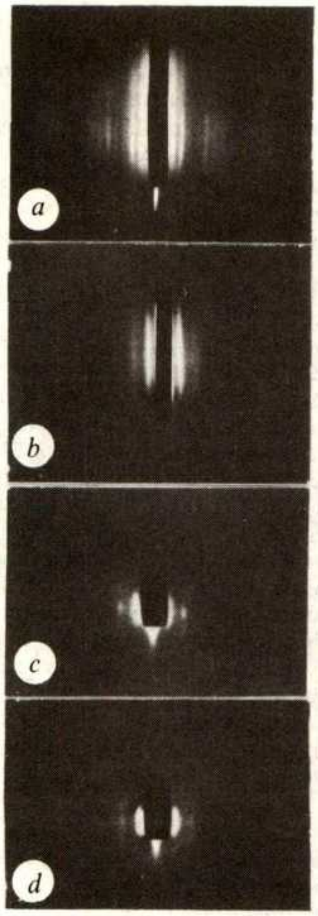

Fig. 1 *a*, Low angle X-ray diffraction pattern of squid retina after fixation in glutaraldehyde. The X-ray pattern was obtained using slit collimation and a specimen-to-film distance of 9 cm. Orders $h = 2$ to 8 of $d = 620$ Å and a diffuse reflection centred at $d \sim 48$ Å are visible. Scattering close to the beam stop obscures the first order of diffraction. *b*, Low angle X-ray diffraction pattern of squid retina after fixation in glutaraldehyde. The X-ray pattern was obtained using slit collimation and a specimen-to-film distance of 20 cm. The first two orders of $d = 620$ Å are visible. The first order has a strong intensity, whereas the second is comparatively weak. *c*, Low angle X-ray diffraction pattern of squid retina after fixation in glutaraldehyde. The X-ray pattern was obtained using pinhole collimation and a specimen-to-film distance of 15 cm. The (01) and (10) reflections on the first layer line are off-meridional but appear to overlap as they have strong intensity. Three reflections are seen on the second layer line. The (11) reflection is on the meridian, whereas the (02) and (20) reflections are off-meridional. *d*, Low angle X-ray diffraction pattern of squid retina after fixation in glutaraldehyde. The X-ray pattern was obtained using pinhole collimation and a specimen-to-film distance of 15 cm. Less X-ray exposure was used to obtain this pattern. The (01) and (10) reflections on the first layer line are resolved as off-meridional reflections. The three reflections on the second layer line are also visible but faint.

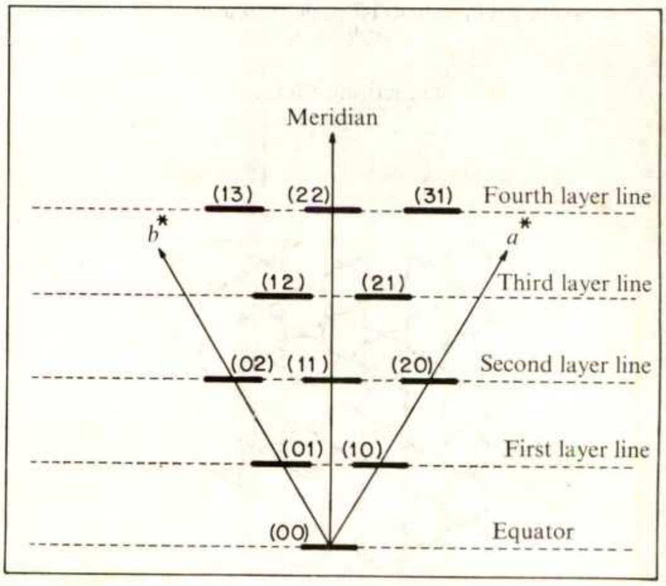
direction, was recorded. Generally, the first three orders of diffraction were discrete, whereas the higher orders merged together. When moderate exposure times were used the X-ray pattern extended out to a resolution of about 20 Å. Occasionally, the first eight discrete orders could be seen. A low angle X-ray diffraction pattern, showing discrete orders $h = 2$ to 8 of a lamellar repeating distance of $d = 620$ Å and a diffuse reflection centred at $d \sim 48$ Å, is reproduced in Fig. 1*a*. The first order of diffraction $h = 1$ is not resolved in Fig. 1*a* because of scattering close to the beam stop. In an X-ray experiment using less exposure time and an increased specimen-to-film distance of 20 cm the first two diffraction orders $h = 1$ and 2 of $d = 620$ Å were recorded. This pattern is reproduced in Fig. 1*b*.

Unfortunately, the interpretation of the low angle X-ray patterns obtained using slit collimation is not straightforward. The first step in interpreting the lamellar diffraction is to identify the orientation of the two-dimensional arrays relative to the light direction. The orientation of the arrays of microvilli is not easily obtained from a study of electron micrographs[7,8]; and, so far, the orientation has not been established by electron microscopy. The recording of discrete orders of a lamellar repeat distance in the slit-collimated X-ray patterns indicates that the microvilli arrays have the same lattice dimensions and that they have the same orientation relative to the light direction. Thus it is important to verify whether the lattice is hexagonal, to establish the lattice dimensions and to determine the orientation of the microvilli arrays relative to the light direction.

The orientation of the two-dimensional arrays of microvilli has been determined by recording low angle X-ray diffraction patterns using pinhole collimation. The pinhole-collimated X-ray patterns require longer exposure times because of the weaker main beam and because of having to use a specimen-to-film distance of 15 cm to resolve diffraction orders along the layer lines. So far, only the first few diffraction orders have been recorded. Typical low angle X-ray diffraction patterns of squid retina are shown in Fig. 1*c* and *d*. The angle between the off-meridional reflections in our pinhole-collimated X-ray patterns is close to 60°; and therefore it is assumed that the microvilli lattice is hexagonal. Note that the angle appears to be slightly less than 60° (it is about 55° in Fig. 1*c* and *d*), indicating that our X-ray specimens contain a microvilli lattice which is slightly compressed along the (1,1) direction. This slight compression probably arises as a result of sectioning and mounting the retina strip in the specimen chamber. The pinhole patterns do not reproduce well, but the off-meridional reflections (01) and (10) on the first layer line and the (11) meridional reflection and the weaker off-meridional reflections (02) and (20) on the second layer line can be seen in Fig. 1*c*. The off-meridional reflections (12) and (21) on the third layer line can be seen in the original negatives. In Fig. 1*c* the off-meridional reflections (01) and (10) are overexposed and tend to overlap in the reproduction. The pinhole pattern shown in Fig. 1*d* has less X-ray exposure and the (01) and (10) off-meridional reflections on the first layer are seen as discrete reflections. A drawing of the pinhole-collimated X-ray patterns

Fig. 2 A drawing of the two-dimensional microvilli lattice as shown by the pinhole collimated X-ray diffraction patterns. The light direction is along the meridian. The a^* and b^* axes of the hexagonal reciprocal lattice is indicated and the (11) direction is along the meridian. The reflections (01), (10), (11), (02), (20), (12) and (21) on the first three layer lines have been seen in a number of negatives. The reflections (13), (22) and (31) on the fourth layer line have not been recorded but are included for illustrative purposes. Note that this figure is rotated 90° relative to Fig. 1 so that the beam stop is along the equator.



is shown in Fig. 2. Note that Fig. 2 is rotated 90° relative to Fig. 1 so that the beam stop is along the equator. The two-dimensional array is hexagonal with $a = 620$ Å and the light direction is coincident with the (11) direction of the two-dimensional arrays. The orientation of the two-dimensional array of microvilli relative to the light direction is shown in Fig. 3.

It is known from electron microscopy[7,8] that the adjacent microvilli arrays of different retinula cells are approximately perpendicular to each other but it is not known to what extent this kind of packing is followed throughout the whole retina. If the X-ray specimen of squid retina contained only two orientations (which are perpendicular to each other) then the recording of the off-meridional reflections would be sensitive to the direction of the incident X-ray beam. But no such sensitivity has been recorded. The pinhole-collimated X-ray patterns indicate that the (11) direction is a rotation axis. Thus, although adjacent arrays may be perpendicular to each other[7,8], this kind of packing is not maintained over the whole retina.

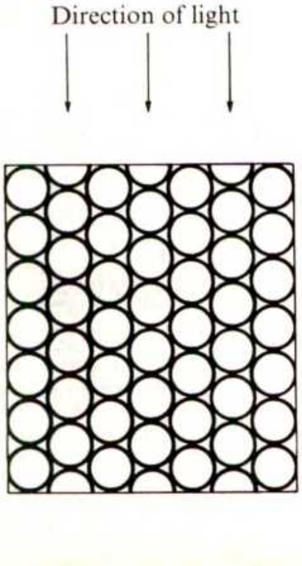
A model for a single microvillus is a long thin cylinder where the wall is made up of a single membrane of width m. It is assumed that $m \sim 75$ Å—that is, the microvillus membrane has the same thickness as the disk membrane[1–4]—and that the outer surfaces of the cylinders are separated by a fluid layer about 5 Å wide. The single membrane is centred at a distance r from the axis of the cylinder and $r = 1/2\ (620-m-5)$ Å, that is, $r = 270$ Å. The Fourier transform of the membrane with respect to its centre is denoted by $M(R)$ where R is the reciprocal space coordinate. The Fourier transform of the two-dimensional array of microvilli is denoted by $T(R)$; and using X-ray diffraction theory appropriate to concentric membrane layers[11], $T(R)$ can be written

$$T(R) \sim 2\pi r J_0(2\pi r R) M(R) \Phi(R)$$

where J_0 is the zero-order Bessel function and Φ is the interference function for the two-dimensional array.

A test of the correctness of the above model can be made by comparing the calculated and observed intensities for the (10), (11) and (20) reflections. In the squid retina the two-dimensional arrays of microvilli are effectively rotated about the (11) direction. To refer intensities to an unrotated array the following corrections are made. The off-meridional reflections (01),(10) and (12),(21) are increased four to five times, while the off-meridional reflections (02),(20) and (13),(31) are increased eight to ten times. The X-ray intensities for the first three reflections of the unrotated array have the following variation: $I(10) \gg I(20) > I(11)$. To calculate intensities from our model it is necessary to first estimate values of $M(R)$, the Fourier transform of the microvillus membrane. For the first two or three reflections which correspond to very small angles of diffraction, $M(R)$, can be approximated[11] by a membrane of constant density so that $M(R)$ is proportional to $(1/R)\sin(\pi m R)$ and where $m \sim 75$ Å. The $J_0(2\pi r R)$ variation is sensitive to the choice of r and we use $r = 270$ Å. By combining the $M(R)$ and $J_0(2\pi r R)$ variations, our model provides an intensity variation for the first three reflections, which is the same as recorded experimentally. Thus, the observed intensities of the first few reflections in the pinhole-collimated X-ray patterns are in agreement with the microvillus membrane having a thickness of about 75 Å and with the concentric membrane having a radius of about 270 Å.

Fig. 3 A drawing of a section through the two-dimensional hexagonal array of microvilli. The section contains the light direction and is perpendicular to the long axes of the microvilli cylinders.



In summary, it has been possible to record X-ray diffraction from the photoreceptor structures of squid retina. So far, these X-ray patterns refer to fixed eyes. X-ray analysis of the pinhole-collimated patterns has provided information on the dimensions of the microvilli and on the molecular organisation of the microvilli in the distal segments of squid retina. Information on the internal structure of the microvillus membrane has not been obtained but this information may be forthcoming in future work provided that more reflections can be recorded in pinhole-collimated X-ray patterns.

Corrigendum

In the article "Intact 3′ end of 16S rRNA is not required for specific mRNA binding" by J. V. Ravetch and K. S. Jakes (*Nature*, **262**, 150; 1976) the sentence at the beginning of paragraph 4 should read "The colicin-treated ribosomes used in the experiment shown in Fig. 1 were lowered in their ability to carry out f2 RNA-directed protein synthesis by 75%" and not as printed.

Errata

IN the article "Constraints on the nature of the ancient lunar magnetic field" by J. N. Goswami (*Nature*, **261**, 675; 1976) two lines were omitted from the end of page 676. The sentence 'One of these . . . Fe–FeS . . . ' should continue ' . . . melt a few hundred kilometres below the lunar surface, initiating such local fields[13] on the Moon, is yet to be verified.'

The title of the article by M. S. N. Carpenter and L. Civetta (*Nature*, **262**, 276; 1976) should read "Hercynian high pressure/low temperature metamorphism in the Ile de Groix Blueschists" and not as printed.

matters arising

Ionic clustering and collagen specificity

PIEZ and Torchia[1] agreed with us[2] that pairs of unlike charged residues in the collagen amino acid sequence are important for the assembly of molecules into fibrils. The described their use of three-dimensional molecular models to examine specific interactions and in doing so criticised our earlier one-dimensional treatment, in particular the dipole formalism used.

One-dimensional analyses of the collagen sequence proved fruitful in earlier work, when it was found that two-thirds of the charged amino acid residues behaved as if they were arranged in pairs of unlike charge[3,4]. We simplified our calculations by treating these 100 paired charges as 50 dipoles; an approach commonly used as, for example, in the treatment of dielectric materials.

Contrary to the belief of Piez and Torchia, our aim was not to suggest a detailed interaction scheme of the type shown in their Fig. 1*a;* we were only suggesting an important role for the paired charges in specifying an inter-into fibrils. They described their use of molecular 1 D stagger. It is difficult to extrapolate this result to determine details of the arrangement of interacting charged residues in three dimensions. Nevertheless paired, unlike unpaired, charges are distributed in the collagen sequence in a manner which is intimately associated with the D stagger[5]. An understanding of this specificity in three dimensions, whether or not the concept of charge clustering is invoked, must await the outcome of a full three-dimensional analysis.

PIEZ AND TORCHIA REPLY—We are pleased to read the statement of Doyle *et al.*[1] that we[2] inferred more from their dipole treatment[3] than they meant us to. We would point out, however, that our Fig. 1*a* is essentially identical to their Fig. 1*b*. In any case, we seem to be agreed that charge groupings (pairs or clusters) are associated with molecular packing of collagen and that a three-dimensional analysis is needed to sort out exactly how they are associated.

A recent rereading of the early literature has reminded us that charge clustering is not a new idea. It was originally proposed by Hodge and Schmitt[4] from electron microscopic studies of positively stained native collagen fibrils and SLS segments. We are, however, now able to treat the question at a much higher degree of resolution.

Retinal sensitivity to short wavelength light

THE recent article[1] on potential hazards due to exposure of the primate retina to visible radiation of short wavelengths contains a number of conclusions which are open to argument.

The lesions are believed to be mediated essentially by (unspecified) photochemical mechanisms. The reciprocity law is not, however, obeyed in the data shown in Table 1, although both human rods and human cones[2] obey it in the timespan used by the authors. The contribution of thermal effects is minimised even though the action spectrum bears a striking similarity to the absorption spectrum of melanin[3].

The protection afforded by the crystalline lens is emphasised in so far as the retina is concerned, although the vitreous may be at risk in aphakic eyes[4,5].

The morphology of the lesion is virtually ignored, even though it has been successfully studied elsewhere[6].

The authors write that a threshold lesion occurs when one views the Sun for not less than 100 s. In our view it should not be implied that a shorter period is safe in their experimental conditions.

HAM REPLIES—According to our best judgment, there are at least three types of radiation damage to the retina in the spectral range, near infrared to near ultraviolet (1,400–400 nm). These are: sonic transient or shock damage from picosecond to nanosecond pulses[1–3], thermal damage (independent to a first approximation of wavelength) from microsecond to second pulses[4,5], and photochemical damage from long term exposure (>1 s) to the shorter wavelengths in the visible spectrum (approximately 500–400 nm)[6]. There is no sharp transition between these three types of retinal damage, either from the standpoint of wavelength or exposure time. We believe that Marshall's report[8] of retinal damage belongs in the general category of thermal damage as outlined here.

In response to the specific comments of Marshall and Weale[7] we offer the following: (1) Not even thermal lesions obey a reciprocity law[4]. There is no particular reason to believe that long term photic damage should obey a reciprocity relation and, as we pointed out in the paper[8], we do not know the relationship of rods and cones to the observed funduscopic pathology. (2) Thermal effects are minimised only for long term exposure to the shorter wavelengths in the visible spectrum where maximum temperatures in the retina do not exceed a few °C above ambient. The absorption spectrum of melanin would be expected to correspond to the action spectrum for thermal damage. Our action spectrum includes both thermal and photochemical damage and its relationship to the melanin absorption spectrum is suspect but should not be overlooked. (3) The hazard to the retina rather than the vitreous for aphakic eyes is emphasised because the vitreous does not absorb radiation appreciably between 300 and 1,400 nm (ref. 9). (4) The morphology of the lesion is not ignored but undetermined to date. Extensive efforts are under way, using both light and electron microscopy, to determine the nature of the lesion. The subtleties of these lesions bear no relationship to those reported by Marshall *et al.*[5]. Calculations show that the minimal irradiance on the retina in their experiments was greater by a factor of 10^3 than those we reported[8]. In other words, Marshall *et al.*, were dealing with a totally different phenomenon, thermal injury, whereas we were seeking to characterise a long term photic damage mechanism or mechanisms in the retina.

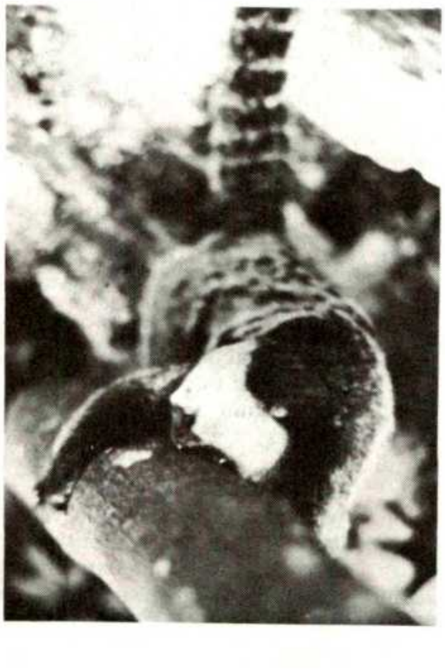
Exudate-eating and tree-gouging in marmosets

KINZEY *et al.*[1] discuss an unusual sap-eating behaviour in the pygmy marmoset (*Cebuella pygmaea*) of upper Amazonian South America. We have observed similar exudate-eating behaviour patterns in southern Brazilian marmosets of the genus *Callithrix* and and would like to discuss briefly their significance.

Like *Cebuella*, *Callithrix* spp. are "short tusked"[2]: in other words, they have an unusual lower anterior dentition in which the canines are short and the incisors long and roughly equal in length to the canines. The other two callitrichid genera, *Leontopithecus* and *Saguinus*, are "long tusked", with normal, long lower canines and short lower incisors. In *Callithrix* and *Cebuella*, the "short tusked" lower anterior dentition is apparently used as a gouge or scraper to perforate the bark and the superficial layer of the cambium of certain trees. When attacked in this manner, the trees exude gums and sap which are important food sources for the marmosets.

Free-living *Callithrix jacchus* have been observed gouging several species of trees (*Anacardium occidentale*, Anacardiaceae; *Tapirira guianensis*, Anacardiaceae; *Terminalia catappa*, Combretaceae) in the Brazilian states of Alagoas and Rio de Janeiro. Favourite trees are sometimes riddled with holes on all surfaces. Captive *Callithrix* (including *C. flaviceps*, *C. geoffroyi*, *C. jacchus* and *C. penicillata*) gouge holes in fresh branches and also in the dry wooden fixtures of their cages (Fig. 1). In addition to feeding on exudates that flow from holes in the fresh branches, captive (and probably also wild) *Callithrix* use the holes in both dry and fresh wood as foci for marking behaviour. High-ranking males and females frequently urinate in them and genital-rub in their vicinity. The gouging process in *Callithrix* is usually accomplished by anchoring the upper incisors on the substratum and scraping with the lower anterior teeth (Fig 1). In both *Cebuella* and *Callithrix*, wear patterns on the occlusal surface of the upper incisors indicate that they are used to hone the tips of the lower incisors (personal communication from R. D. Martin). Depending on their hardness, exudates are either licked up or collected with teeth. In contrast to *Cebuella* and *Callithrix*, the "long-tusked" *Leontopithecus* and *Saguinus* have never been observed gouging holes in wood, although they occasionally chew on strips of bark and feed on already-exuded gums if they happen to come across them.

Fig. 1 Captive *Callithrix geoffroyi* gouging hole in dry branch in its cage. Note the positions of the upper and lower teeth.



An analysis of the gum of *Anacardium occidentale* gives an indication of the food value of exudates. The gum of this species is 84% carbohydrate and contains several minerals, including iron, aluminum, calcium, silicon, potassium and traces of magnesium and sodium[3]. These substances therefore provide small primates like *Callithrix* and *Cebuella* with a high energy food source not used to any great extent by larger primates and other potential competitors, and helps them to, at least in part, avoid competition for fruit, the major high energy food source for many tropical mammals and birds.

Sporadic exudate-eating from sites where insect infestation or mechanical damage has caused it to flow is a fairly common pattern in primates. The same can be said for occasional use of the teeth to pry, gouge, strip or break bark from trees. In addition, certain prosimians (for example, *Euoticus elegantulus*, *Microcebus murinus* and *Galago senegalensis*) use their specialised "tooth combs" or "tooth scrapers", formed by the lower anterior dentitions, as scoops to collect gums from areas where they have already exuded (personal communication from R. D. Martin). But, the regular use of tree gouging specifically to elicit exudate flow has so far been found only in *Callithrix*, *Cebuella* and the Madagascan fork-marked dwarf lemur *Phaner-furcifer*[5] and seems to be rare not only among primates but among vertebrates in general.

Shadowy threshold

THE ridiculous consequences of the threshold nuclear test-ban treaty, pressed on an unwilling world in 1974 and scheduled to take effect in April 1976, begin to make themselves known. The treaty is a strictly bilateral affair between the United States and the Soviet Union and the two parties have agreed to restrain weapons to yields not exceeding 150 kilotons. A related treaty covered peaceful nuclear explosions. Although formal ratification is still awaited, both parties have been honouring the treaty for some months.

In 1974 there was vigorous criticism of almost all aspects of the treaty in many parts of the world: a bilateral treaty was too coy; the threshold was too high for any sensible arms control purposes; the complications of geology made accurate seismic monitoring of the threshold difficult. On the last count, the period of nearly two years between proposal and enforcement was put forward by the treaty's proponents as a time when data exchange would allow accurate calibrations of test sites to be made. Certainly there was a mild flurry of activity as scientists moved between capitals clutching seismograms. But on July 4, in the case of one of the first tests to be fired by the Soviet Union since the April deadline, there was a sufficient element of doubt in American official quarters to push the whole concept of the treaty right back into the public arena. The arguments have since continued.

No official American estimate of the yield has been forthcoming but the figures first being passed around were 100 to 200 kilotons; a later figure to be mentioned was "exactly 150 kilotons". In the midst of all this an unpublished understanding between the two powers was wheeled out, to the effect that "technical uncertainties . . . may result in slight unintended breaches . . . one or two such per year would not be considered a violation of the treaty". In other words, since yields can be predetermined to within a few per cent knowing the conformation of the device, at least one party to the treaty—probably the Soviet Union—intended to test right up to the threshold. Some arms control measure.

There has been much justifiable tut-tutting over these loose edges to the treaty in the past week, but little about the calculations which have helped provoke it. Yet there is a vast amount of seismic data in the public domain and this explosion will have been excellently recorded all over the world. United States government estimates take into account we know not what, but it is open to anyone else to make his or her own reasonable estimate. There are published papers giving clear recipes for how to convert a seismic signal to explosive yield, with the help of some modest knowledge of Soviet geology. And when we do the sums we can't see how the yield can be much more than 100 kilotons.

The cause of the discrepancy is an old problem. It is easiest to measure the yield seismically by observation of the so-called body waves generated by the explosion. These have the larger signal-to-noise ratio and are measured routinely. The so-called surface waves from blasts, on the other hand, are smaller and need a little more time for their analysis. But at the sort of yields we are talking about there begin to be discrepancies between yields from the same explosion measured routinely by the two techniques—and there are good theoretical grounds for favouring the surface-wave method.

In the past, the body-wave method has been known seriously to overestimate the yield. This has led to the publication of information about the yields of Soviet tests, placing them in the multi-megaton region when the yield has probably been barely a megaton. Admittedly all estimates of seismic yield are accurate only to perhaps 20%. But now we see an old problem emerging to befuddle the issue of the threshold treaty, which is made to look silly right from the word go. One wonders whether the two years could not have been more profitably spent in avoiding such a hassle. □

Toxic cloud over Seveso

The fall-out from last month's explosion in Italy involves more than dust, as **Alastair Hay** points out

ON JULY 10, an explosion at a chemical factory in the North Italian town of Seveso released a cloud of vapour which contaminated the surrounding area. The vapour, a chemical cocktail consisting primarily of trichlorophenol (TCP), also contained an extremely toxic by-product, TCDD (2,3,7,8 - tetrachlorodibenzopara - dioxin), a virulent poison.

It happened six and a half hours after the plant, belonging to Givaudan ICMESA, a subsidiary of Hoffman-La Roche, had closed down for the weekend. There was a "runaway reaction" in the reactor producing trichlorophenol. The pressure increased as the reaction became exothermic, and reached the critical limit, blowing the safety valve and thus discharging the reactor contents. The valve, situated outside the plant, discharged the hot vapour directly into the atmosphere. When the solvents evaporated, trichlorophenol crystals and 2 kg of TCDD, in the form of dust, were precipitated south of the factory over an area inhabited by some two thousand people.

Local police were informed of the explosion on the day that it occurred; the following day the mayor of Seveso was told; and on Monday, July 12, ICMESA notified the local authorities of areas bordering on Seveso. A statement was issued by these local officials, warning against the consumption of fruit and other crops from the area surrounding the factory. On July 15, the first animal deaths were reported. The first reports of children suffering from skin rashes came a day later. By July 22, when over thirty people were reported to be showing symptoms of burns and poisoning, local authorities were still insisting that there was no cause for panic. No general evacuation had been planned.

Not until two weeks after the explosion was TCDD first identified, by a provincial diagnostic centre. The identity of the dioxin was confirmed by Givaudan three days later, on July 26. Local officials had meanwhile been alerted to the seriousness of the situation by the ICMESA management, and on Tuesday, July 27, fully 2½ weeks after the explosion, evacuation began, at first only of children. Since then the known area of serious contamination has grown severalfold, and by the middle of last week over 800 people had been evacuated from this zone. Another 1,300 children had been evacuated, as a precautionary measure, from the area outside that of immediate contamination.

Delayed action

Only after it had been established that TCDD had also been released in the vapour cloud did the authorities realise the need for urgent action. Up to this point, the information supplied to them by the ICMESA management had implied that the worst component of the vapour was trichlorophenol. This undoubtedly led the local authorities to believe that the situation, although serious, did not warrant a general exodus from the contaminated area.

It is this delay which has given cause for concern, particularly in view of the known toxicity of the dioxins. Experimental evidence is available of the effects of TCDD on a range of animals, and is to be found in the US National Academy of Sciences (NAS) document *Effects of Herbicides in South Vietnam*. A single dose of this dioxin is lethal in guinea pigs at a concentration of $0.6\,\mu g\,kg^{-1}$. In male rats the lethal dose is $22\,\mu g\,kg^{-1}$; in rabbits $115\,\mu g\,kg^{-1}$; and in humans, it has been calculated to be less than $5\,mg\,kg^{-1}$. This means that the toxicity of TCDD can be compared to that of strychnine.

Clinical signs of TCDD poisoning include atrophy of the kidney; necrotic changes of the liver; ulceration of the stomach; haemorrhages in the gastrointestinal tract and other organs; and atrophy of the thymus and other lymphoid organs and tissues. The latter changes are those most commonly observed.

Teratogenicity of TCDD has been demonstrated in mice, although evidence of teratogenic effects in other animals is more equivocal. According to Neubert *et al.* (*Environ. Health Perspectives*, Exp. Issue No. 5, 67–80; 1973), when TCDD was given to mice daily on days 6 to 15 of pregnancy, at least 50% of the progeny exhibited kidney anomalies at concentrations of $1\text{–}3\,\mu g\,kg^{-1}$; death occurred at concentrations of $7\,\mu g\,kg^{-1}$.

Reports from Seveso confirm that 500 people are being treated for poisoning. Many are showing symptoms of kidney and liver malfunction. Others from the area affected by TCDD fall-out have chloracne, a persistent and disfiguring form of acne associated with contact with chlorinated compounds. If treated, the acne may clear up in six months. There is evidence, however, of a worker in a chemical factory producing chlorophenols who is still disfigured 15 years after exposure to the chemicals.

AP

Not the first time

As the painful assessment begins of the effects of the dioxin contamination, evidence has accrued almost daily of chemical explosions involving trichlororophenol production which have already occurred and which were similar to the one at the ICMESA plant.

The first accident occurred in 1953 at the Ludwigshafen works of the Badische Anilin und Soda Fabrik AG (BASF) in Germany. Fifty-five workers were exposed to dioxin, all of whom developed chloracne. Twenty-one developed symptoms of systemic poisoning, including damage to the liver, kidney and spleen; the heart, respiratory tract, eyes and nervous system were also affected. Five years after the accident, a worker engaged on repair work on the site developed symptoms of dioxin poisoning; nine months after the appearance of the first symptoms, this worker died from an inflammation of the pancreas. Following medical advice, BASF later stopped production of trichlorophenol.

In 1963, at the Philips Duphar complex in Amsterdam, an explosion released between 30 and 200 g of dioxin into the factory hall. Fifty people were affected, at least ten of whom are still suffering from skin complaints. Four workers died within two years of the accident, but there is no proven connection between their deaths and dioxin poisoning. After an unsuccessful attempt to remove dioxin from the factory walls, the firm closed down the trichlorophenol plant for ten years. When information on dioxin contamination had been reviewed, the only course of action open to the company was to dismantle the plant brick by brick working from the inside outwards. The rubble, embedded in concrete, was eventually dumped into the Atlantic.

At the Coalite and Chemical Products plant at Bolsover, Derbyshire (UK), seventy-nine men developed chloracne following an explosion at the trichlorophenol plant in 1968. Since the Seveso accident, this firm and the West German firm of Bayer of Leberkusen have both temporarily ceased production and are reviewing their manufacturing procedures.

The most disturbing reports relating to dioxin poisoning, however, are undoubtedly those from Vietnam. Increasing criticism of the American use of herbicides in the war in Indochina resulted in the National Academy of Sciences conducting a thorough investigation. The report of their findings, published in 1974, has been criticised over its interpretation of the data concerning deaths and birth defects in communities sprayed with herbicides. In an introduction to the report, Dr Philip Handler, the NAS President, claimed that no definite connection existed to confirm findings of herbicide-induced birth defects or deaths.

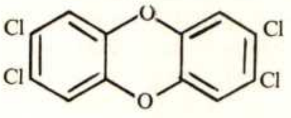
The NAS report itself does, however, contain considerable information about the effects of herbicides and the contaminant TCDD on humans, animals and vegetation in Vietnam. One anthropologist who submitted evidence to the NAS study, Dr Gerald Hickey of the South-East Asia Programme of Cornell University, has reported evidence of deaths from among the children of the Montagnard peoples of South Vietnam, deaths directly related to herbicide spraying. The first-hand interviews he conducted with Montagnard villagers revealed the additional evidence that other children had shown symptoms such as skin rashes, diarrhoea and abdominal pains.

Hickey was cautious in attributing these effects directly to TCDD; the evidence is more circumstantial. During the Vietnam war, the Americans repeatedly sprayed these mountainous areas of South Vietnam, inhabited by the Montagnard people, with the herbicide "Agent Orange", a 50 : 50 mixture of the n-butyl esters of 2,4-D (2,4-dichlorophenoxyacetic acid) and 2, 4, 5-T (2,4,5-trichlorophenoxyacetic acid). The dioxin TCDD is a contaminant present in 2,4,5-T at levels variously estimated at between 0.07 and 50 p.p.m.

Although the NAS report claimed that no evidence is available to substantiate herbicide-induced birth defects in humans, the Italian authorities are currently paying serious attention to the advice of a Vietnamese doctor. Professor Ton That Tung of the Viet Duc Hospital in Hanoi insists (in *Vietnamese Studies*, **29**, 53–81; 1971) that such evidence is available.

Unanswered questions

Certainly the assembled evidence points to some unanswered questions. Because previously recorded accidents at other trichlorophenol-producing plants had released TCDD, the chance existed that the same would be true in any accident at Seveso, and the authoritites might have expected to have been informed accordingly. But even in the unlikely event that the ICMESA management was unaware of the historical evidence pointing to this danger, simple theoretical knowledge of the factors favouring TCDD production should have alerted them to the possibility of dioxin contamination. Moreover, the plant's safety valve was situated outside the plant, allowing a discharge of vapour directly into the atmosphere. This served to protect the plant itself from the vapour, but did so at the cost of serious contamination of the surrounding countryside.



TCDD

(2,3,7,8-tetrachlorodibenzopara-dioxin)

TCDD is produced as a by-product during the alkaline hydrolysis of tetrachlorobenzene with methanolic sodium hydroxide to form 2,4,5-trichlorophenol **(1)**.

Trichlorophenol is both the industrial precursor of 2,4,5-T (2,4,5-trichlorophenoxyacetic acid), a herbicide normally used in esterified form as the butyl ester **(2)**, and an intermediate product in the manufacture of hexachlorophene, an antibacterial agent added to soaps, shampoos, deodorants and toothpastes.

The hydrolysis of tetrachlorobenzene is carried out at high temperatures and under pressure. This reaction, if not very carefully controlled, is favourable to the formation of TCDD, the most common chlorodibenzoparadioxin present in 2,4,5-T. Other toxic polychlorodibenzoparadioxins are also produced in the manufacture of chlorinated phenols.

Theoretically, at least 75 different chlorodibenzoparadioxins can be predicted having one to eight chlorine atoms attached to the two benzene rings. At least ten have been synthesised, and one or two more have been found in food, animal feeds and 2,4,5-T.

Hexachlorophene is prepared by the condensation of two molecules of 2,4,5-trichlorophenol with formaldehyde in the presence of concentrated sulphuric acid **(3)**. The preparation procedure has been improved, and the Givaudan Corporation hold the US patents Nos. 2,435,593 (1948) and 2,812,365 (1957).

Properties of TCDD

Like other chlorodioxins, TCDD is stable to heat, acids and alkali; a temperature of 800 °C is required for thermal decomposition. TCDD is virtually insoluble in water (0.0002 p.p.m.), only slightly soluble in fats (44 p.p.m. in lard oil), more soluble in hydrocarbons (570 p.p.m. in benzene), and at its most soluble in chlorinated organic solvents (1400 p.p.m. in ortho-dichlorobenzene).

Uptake of TCDD occurs slowly in plants (oats and soybeans). No accumulation above external concentration occurs, however, and plants grow to maturity (A. R. Isensee and G. E. Jones, *Agric. Food Chem.*, **19**, 1210–1214; 1971).

TCDD is almost immobile in soil. Even in very porous soil it remains close to the point of application (P. C. Kearney *et al.*, *Environ. Health Perspectives*, Exp. Issue No. 5, 273–278; 1973).

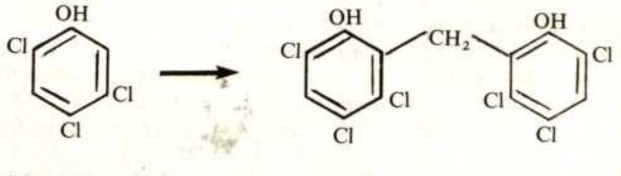
2,4,5-trichlorophenol 2,4,5-T



(3)

2,4,5- trichlorophenol hexachlorophene

The question of decontamination is now presenting Givaudan, Roche and the Italian government with serious problems. An Italian government commission recommended removal of topsoil to a depth of 10 cm in an area of 280 acres, the dismantling of all buildings in the Seveso area and the total disruption of all wildlife. These recommendations may take up to three years to implement. The sheer volume of soil to be processed and the number of buildings involved will create enormous technical problems of disposal. Great care will have to be taken to avoid further contamination by TCDD when material is removed from Seveso.

The British firm of Cremer and Warner have been retained by Givaudan to help in the task of decontamination. Cremer and Warner are chemical engineers specialising in the environmental safety aspects of industrial pollution. Data already accumulated indicate that the intensity of contamination does not conform to any uniform pattern, and the feeling is that it would be premature to implement the Italian commission's proposals, at least until potential alternatives are considered.

But no one doubts that a satisfactory policy for accident prevention and control can possibly be formulated if vital information is withheld from those whom it may affect most directly. In Seveso, the local mayors did make attempts to find out what was actually being produced at the ICMESA plant. But that was four years ago. Only last year did Givaudan finally provide some information. No mention was made of the dioxin risk, and therefore no safety measures were suggested. Even now there is conflicting information about the processes for which the ICMESA works were designed. One senior Roche executive has said the plant was producing trichlorophenol for the manufacture of the herbicide 2,4,5-T; another spokesman claimed that the plant was making trichlorophenol for the manufacture of hexachlorophene at another site.

Few unaffected

Few people have been uninvolved by the actions of the Roche subsidiary. Scientists and engineers at the Seveso plant failed to predict the extent of dioxin contamination and its spread over the countryside. Workers at the factory demanded to know of any dangers involved. Management did not inform them until two weeks after the explosion. Local residents knew nothing of the real hazards of the contamination. The medical profession, lacking an antidote, must give only symptomatic treatment. Pregnant women, agonising over the teratogenic effects of TCDD, must decide with little firm guidance from the Church whether to undergo abortions. Ecologists cannot predict the long term effects of dioxin contamination. The authorities know that the decontamination proposals themselves are at best a mixture of policies adopted at previous accidents, leavened with a good deal of hope.

The suggestions being made now involve at the very least the implementation of strict codes of practice, to be adopted between industrial concerns and the local authorities to which they bear a great measure of responsibility. Such codes would include detailed procedures to be followed in the event of an accident. As for the withholding of information, few are accepting the obvious convenience this represents for manufacturers as a satisfactory explanation. Many are saying that with all the facts more freely available, it may, for example, be decided that the risks involved in producing trichlorophenol outweigh the necessity of a 2,4,5-T weedkiller—or a TCP mouthwash. Only the inquest now to come will reveal whether some sort of political solution is needed to ensure that the necessary information is available and to prevent a recurrence of this kind of disaster. □

Europe's ageing research staffs

Mike Duckenfield reports from Stockholm on the problem of an "unhealthy" age profile among researchers and teachers

WITH one or two exceptions, notably Finland where spending is to be increased from 1% to 1.7% of the GNP during the next five years, research budgets in most Western European countries are having a struggle to keep pace with rising costs. Not only is government spending being cut back or slowed down, but what funds there are available are being affected by an incremental drift of salaries as young staff get older and, as in Britain and the USA, increasing unionisation. Even in Norway, where unemployment is well below 2% and economic growth at a steady 7%, the prospects for those wanting research jobs are very slim.

Graduate unemployment is a problem in itself, but there is also another side to the coin: the likely prospect of universities and research institutes in most nations losing a generation of teachers and researchers during the next 15 years due to the lack of job opportunities. The problem, in short, is that the universities are now moving into the shadow of the massive expansion of higher education which took place in the 1960s. Due to this boom the average age of teachers and researchers is now very low, retirements are relatively few and future openings for new blood and ideas drastically diminished. According to academics in several countries, promotion, mobility and possibly even creativity are all likely to suffer.

The problem of an "unhealthy" age profile among researchers and teachers is beginning to be studied in nations ranging from France to Norway. Due to large scale recruitment in the middle and late 1960s, too large a proportion of staff are now only at the beginning of their careers. A recent Federal German survey shows that while 45.9% of professors and senior lecturers in 1966 were over 50 years old and only 22.3% under 40, corresponding figures for 1972 were 28% and 30.5.%. In addition, while other teaching staff under 35 accounted for 17.4% of the total in 1966, six years later the figure was 27.3%.

In Britain, too, the average age of university teachers has fallen significantly; now 63% of academic staff are under 40, 26% are under 30 and 13% over 50. In Norway 18.8% of staff are over 50 compared with 43.7% under 35, while a survey of French research workers in the Centre National de la Recherche Scientifique showed the average age of those engaged in mathematics was 28 years and 7 months and those in physics and chemistry 34 years and 5 months. In Sweden as many as two-thirds of researchers in some branches of social science are under 35.

With comparatively young staff holding most of the senior positions, future promotion prospects are well below normal. A report prepared for the Council of Europe by Gert Elstermann, academic director of the University of the Saarlands, says that the annual replacement demand for teachers in Federal German universities and colleges up to 1990 will remain much the same as it is at present in law and the social sciences. For other subjects it will stay unchanged until the mid-1980s. Similarly, in Norway prospects for the next 15 years suggest annual recruitment levels below those of any year since the early 1960s. In

•

1972 there were 270 new jobs, this year only about 30 are expected.

Elstermann calculates that while an assistant lecturer in Germany had more than a 70% chance of being appointed as an established university teacher—in many cases as full professors—in the 1960s, in the 1976–85 period these chances will fall to only 15% before rising slowly to 23% in 1990 and 30% in the year 2000. Writing in last year's annual Norwegian research review, Hans Skoie, deputy director of Norway's Science and Humanities Research Council's Institute for Studies in Research and Higher Education, commented: "There is a definite danger that universities and research establishments may develop into communities of senior citizens leaving membership of future classes of graduates with miniscule chances of getting research jobs."

He fears that potential scientists will be discouraged from going on to higher studies and many of the best talents lost. This in turn would lead to less research being performed through thesis work, thereby deteriorating the chances of senior staff to carry out their own projects. The trend against further studies has been evident for several years in neighbouring Sweden. In 1968, 37% of graduates went on to further studies. By 1971 this had fallen to 22.5% and last year it was down to only 14%. The Swedes are especially worried about their failure to attract students in mathematics and the natural sciences.

Another fear is that as the present research population gets collectively older fewer will be likely to change jobs—a trend reinforced by the tight employment market. This lack of mobility could then affect contacts between the universities, research institutes and commercial laboratories, and a Council of Europe report presented recently to a meeting of the organisation's committee for higher education and research concludes that the overall result could be stagnation and a possible decline in research creativity.

Attempts to overcome the age imbalance problem vary widely. In France priority is being given to the recruitment of contractual staff as against creating new tenured positions which would have the status and security of those of civil servants. In Federal Germany the remedy advocated has been a strict adherence to temporary contracts, with nearly all staff below professorial level being untenured, the idea being to maintain a steady flow of young academics through the universities. However, long term solutions of this kind are almost certain to be opposed by the trade unions.

Other suggestions include encouraging older researchers to apply for senior administrative posts, introducing productivity or merit increments instead of those based on seniority or simply age, making the retirement age more flexible, offering increased opportunities for leave of absence, more academic exchange programmes and, perhaps rather optimistically, simply filling staff vacancies as soon as they occur. □

CHEMICAL WEAPONS

Disarmament by phases

At the Conference of the Committee on Disarmament (CCD) in Geneva, Britain last week tabled a draft convention on the prohibition and destruction of chemical weapons to complement the 1925 protocol banning their use in war. Chris Sherwell reports

THE search for a convention to cover unconventional weapons continues. The latest initiative has come from Britain in the sphere of chemical weapons, and, as the UK representative explained to the 720th plenary meeting of the CCD, combines new ideas and constructive and realistic elements from previous drafts into a draft treaty which is being presented as a focus for negotiation.

The 17-Article draft, which the CCD's 30 member states will study before their spring session in February next year, has several features. The emphasis on "confidence building" is one. Under Article II signatories would each establish or nominate a national verification agency; in declaring whether or not they were in possession of chemical weapons and producing figures they would, it is hoped, be generating the confidence without which the main provisions of the treaty would not come into effect.

Article III is also aimed at confidence building. It amounts to a moratorium on production of the chemical weapons specified in a protocol still to be negotiated for Article I, by which signatories would have undertaken "never, in any circumstances, to develop, produce, or otherwise acquire, or use" chemical weapons or munitions or their delivery systems.

Another feature is the draft's three-stage implementation. After the first phase, in which signatories would stop production of chemical weapons and would provide information, the main provisions of the treaty would come into operation. The third stage, marked by Article VII, provides for the phased destruction or conversion to peaceful use of chemical weapons and the destruction of stockpiles. The exact programme is left for negotiation, but a Consultative Committee would arrange for the vital aspects of verification, inspection and exchange of information. Article IX offers a framework, which could also be amplified in a protocol.

Britain does not have any specific time scale in mind for the conclusion of a chemical warfare treaty, and with the summer session of the CCD about to end, is looking only for preliminary reactions. She has shown some eye for timing, however. Eastern bloc countries put up a draft convention in March 1972, as did Japan in April 1974; non-aligned countries had suggested a series of guidelines the previous year. In 1974 Canada suggested the phased destruction of all CW agents. This received the crucial support of the USA in April this year which, in the absence of the promised US–USSR initiative, made this the appropriate time for consolidation.

The time was also right because of technological improvements in monitoring techniques and because the experience of the International Atomic Energy Agency over nuclear safeguards showed that monitoring and protection of military and commercial secrets were not mutually exclusive. The US–USSR agreement earlier this year concerning on-site inspection of "peaceful" nuclear explosions is also regarded as an important breakthrough.

Whether Britain thinks member states now really believe that chemical weapons are unnecessary or that there is no need for stockpiles is another matter; the purpose of the latest proposal, however, is not seen as being to establish which countries are thinking along these lines by discovering their reactions to the draft. A readiness to move forward is apparently perceived, although it is acknowledged that the USSR might choose to describe any concessions it makes over verification in terms of "peaceful collaboration", rather than admit the change. □

COMECON

• The 30th meeting of Comecon in Berlin last month, held to assess the first joint five-year plan and discuss future integration, considered the prospect of integration over a fifteen to twenty year period in certain major sectors, including nuclear power. According to the joint communique of the meeting, there has been a "rapid growth" in the use of nuclear power during the past five years; the present capacity of nuclear power stations in the Comecon countries amounts to 7.5×10^6 MW, with an expected increase by 1980 to 30×10^6 MW, and Mr Kosygin in his address stressed the great importance of the "acceleration of the construction of nuclear power stations".

There have, however, been reports of the breakdown of Interatomenergo, the supranational Comecon body responsible for the construction of nuclear power stations, particularly since, shortly before the meeting, the Hungarian Deputy Premier Istvan Huszar strongly criticised the establishment of such supranational bodies whose policies may well run counter to those of individual members. In fact there seems to be no direct evidence that Interatomenergo (founded in December 1974) has broken down, although power supplies are, indeed, a pressing problem to Comecon.

About half, perhaps more, of the Comecon countries' electricity could be nuclear by 2000, but the short term solution cannot be a nuclear one: immediate plans for the exchange of power resources, which should in turn allow the reserve capacities of individual countries to be reduced, will for the moment be based largely on thermal power stations. Thermal power stations at present contribute some 87% to the total generating capacity of Comecon, and even with the planned nuclear expansion of the next five years, when nuclear power capacity will increase from 2.5% to 8% of the total, the role of the coal- and lignite-powered thermal stations will remain significant.

It seems doubtful that the Comecon countries will be able to fulfil all their long term plans without outside (that is, western) help, however, at least insofar as these plans depend on the development of more advanced reactors, such as the fast breeder, by the USSR. For the moment, though, the focus is on pressurised water reactors of the Voronezh type, which the USSR has developed commercially and can supply to its Comecon partners, including Cuba. And few in the West's nuclear industries doubt the benefits conferred by Comecon's unquantified but adequate uranium resources and by an equally unquantified but certainly unorganised anti-nuclear lobby.

• An agreement between the Comecon countries (including Mongolia and Cuba) on further cooperation in space exploration was signed in Moscow last month. According to Academician Anatolii Aleksandrov, President of the Academy of Sciences of the USSR, the agreement envisages cooperation in launching spacecraft, designing equipment, geological and meteorological surveying, joint technological research and the exchange of scientific data.

Such joint research has, of course, been taking place for some seven years now, under the Interkosmos programme. The latest two satellies in this series, Interkosmos 15 and 16, were launched on June 19 and July 27 respectively, and mark a new development in the programme—the monitoring of data from the satellites by member countries other than the USSR. Suitable receiver stations have already been built in Hungary, the GDR and Czechoslovakia, with Cuba and Bulgaria scheduled to join the monitoring network in the near future. The new Interkosmos satellites carry a special unified telemetry system developed jointly by Hungary, the GDR, Poland, Czechoslovakia and the USSR.

This stress on greater participation by the non-Soviet members of Comecon inevitably invites debate about the further development of the programme. Already there seems to be a trend for countries to specialise in individual fields of the programme. The data on solar radiation being gathered in the current experiments is being processed by a Polish team in Torun, although it is also being assessed in Moscow by the Lebedev Physics Institute, which acts as coordinator. The GDR and Czechoslovakia appear to be especially concerned with the development of sophisticated electronic and optical equipment.

Such devolution and specialisation, if carried through, could well provide a new impetus to a programme in which, to date, one or two non-Soviet experiments at a time have been included in a still largely Soviet project.

The growing participation of member countries in the back-up research for manned space flights is another new feature of Comecon space research. The recent joint "Biosputnik" programme, according to a statement from Professor Stanislaw Baranski, Chairman of the Commission on Biology and Space Medicine of the Polish Academy of Sciences, has shown that three weeks in conditions of weightlessness "posed no danger" to the locomotor system or to muscle and bone tissue, but that the adrenal gland functions "revealed changes typical of stress". Similarly, the Hungarian Joliot-Curie Radiation Biology Institute has developed a model which absorbs various types of radiation in the same way as does the human organism. Although other, more conventional applications of this model are possible, notably in monitoring laboratory and industrial radiation hazards, its application to space research is especially emphasised.

This participation in space biology by the non-Soviet members of Comecon, which will continue with another "Biosputnik" project next year, raises the question of possible participation by Comecon crew members in Soviet space flights. Soviet space planning is greatly influenced by the concepts of Tsiolkovskii, who envisaged a large permanent orbiting space station as a *sine qua non* for any exploration deeper into space, and among the crew of several hundreds which he postulated for such a station, room for a token number of participants from Comecon member countries could presumably be found. The Soviet Academician Boris Petrov, Chairman of the Interkosmos Council, discussing the new Comecon space agreement, has meanwhile said that the Soviet Academy of Sciences is to hold talks in the near future with NASA about further cooperation in manned spaceflight.

Vera Rich

IN BRIEF

Immunisation clearance

A major hurdle to President Ford's $130 million nationwide programme of immunisation against swine 'flu has been removed with the successful passage through Congress of legislation providing for individual claims for damages as a result of inoculations to be filed against the government. Mr Ford last week signed the bill introducing Federal liability following threats of withdrawal from vaccine manufacturers themselves unable to arrange cover with private insurance companies. Under the new law injured parties would sue the government which could in turn sue programme officials accused of negligence or malpractice.

Marine conservation moves

Good news and bad for marine conservationists. The bad news came last week when Britain, having lodged an objection with the North East Atlantic Fisheries Commission against continued overfishing of herring in international waters, itself decided to exceed the commission's recently-set catch quotas. Britain had earlier called for a complete ban on North Sea herring fishing, and only the Norwegian Prime Minister has asked his country's fishermen not to exceed existing catch limits when the exclusive economic zone extends to 200 miles.

The good news arrived with agreement between Brazil, Japan, South Africa and the USSR on catch figures for minke and sei whales in southern oceans over the next year. The new shares are based on reduced overall quotas set by the International Whaling Commission during its recent annual meeting in London.

Animal experiment proposals

A memorandum from a Parliamentary committee urging tighter controls over laboratory experiments with animals is now before the UK Home Secretary, Mr Roy Jenkins. The memorandum calls for new legislation more appropriate to modern experimental requirements, a more stringent system of licensing, and an increase in the number of government inspectors. It also urges an enlargement and greater powers for the Home Office Advisory Committee on Animal Experiments, which has met only 7 times in 10 years. The memorandum marks the launching of Animal Welfare Year and coincides with the centenary of the still current Cruelty to Animals Act. Last year saw a 3.3% drop in the number of experiments with living animals in Britain to just over 5.3 million.

Censor judgment

KENNETH MELLANBY

Progress in science depends on the communication of the results of research between scientists. There are those who think that the usual channels—the learned journals—do this inefficiently, and who propose novel techniques, but in practice the old methods continue. However, journals can only do their job if scientists submit papers describing their work, and if editors select good papers and reject bad ones.

This selection means that some sort of censorship operates, however much we may dislike the idea. Papers are refused because they are badly presented, or because their scientific content is considered unsatisfactory. Unfortunately many scientists cannot write clearly, and some ignore the instructions about presentation given by the journals to which they submit their work. Editors consider themselves justified in refusing badly written papers, but if the work described is good, they should try to encourage the author to resubmit an acceptable draft. Unfortunately few editors have the time to rewrite a manuscript, and therefore the results of some good work may be lost.

Fortunately for editors, in many university departments or research institutes the writings of junior workers are vetted by their senior colleagues, and this may ensure a proper standard of presentation and content. Generally this system works well, but occasionally the publication of valuable results is unnecessarily delayed by what amounts to internal censorship. There are those who are so obsessed by the bogy of premature publication that they always advise, or even insist on, delay. At the same time many scientists find writing up their work to be tedious and difficult, and again they delay publication. Research workers who accept public money and then delay or do not publish their results could be considered guilty of fraud to the scientific community.

To judge the scientific merit of papers offered to them, editors usually rely on expert referees. Most referees take their duties responsibly, and make satisfactory assessments. Unfortunately some referees are prejudiced and recommend rejection of results contrary to their preconceptions; editors must be on their guard against this type of censorship. Even with the greatest care, however, mistakes are made, as it may be hard to distinguish originality from idiocy. Outstanding scientists whose work is rejected may console themselves with the knowledge that, if it is good, recognition will not long be delayed. Unfortunately many of the unrecognised geniuses who complain that their work remains unpublished have little of worth to contribute to science.

The most controversial issue is the use of censorship on moral or ethical grounds. Most scientists consider that certain types of cruel animal experiments should be forbidden, and some journals have a policy of refusing to print articles describing such work. Papers describing what are considered to be unethical medical practices are also refused by a number of editors. At first sight this type of censorship seems to be justified, but has an editor the right to assume this "holier than thou" attitude? If the work is of scientific importance, or is likely to advance medicine substantially, has he a right to suppress it in this way?

If a research worker has done something which is illegal, or which contravenes the conditions of a vivisection licence, he should perhaps be warned of the possible consequences of the publicising of such acts. Editors may need to take legal advice regarding their possible liability for publishing such results. But scientific merit must surely remain the criterion by which scientific research and publication is judged. Unethical practices should be prevented, but not by censorship.

correspondence

Scientists in Argentina

SIR,—My intention in writing this letter is to present another point of view regarding the position of scientists in Argentina. The letter written by 70 Italian scientists (July 22, page 253) has indeed surprised me.

I can remember that a law identical to the one which the Italian scientists referred to (Ley de Prescindibilidad) was passed two years ago by the constitutional government of Argentina. Under that law the Peronist government "released from duty", for "reasons of service" with no further justification, thousands of public workers from both scientific and non-scientific institutions. It is funny that at that time this group of Italian scientists did not air complaints. In this previous instance the Minister of Education of the Peronist government established very clearly a policy inspired by the criterion "who is not occidental and Christian is subversive". He repeated this criterion in several public talks, and again at that time no complaints from this group of Italian scientists were heard.

If scientists are interested in the advancement of science and not in politics then they should be impartial in judging the internal political situations that affect a scientist's work, especially in South America where these problems very frequently arise.

Subversion in Argentina could be found in every department and institution of the government. Subversives are not only those who plant bombs; they are also those who support the "guerrilla" in different ways, those who steal public money and those who use power to their own benefit. Argentina is now fighting for its survival against these groups and fortunately it is winning. Of course there may be some unjustified cases in which an innocent person is "released from duty", but many more innocent people lost their lives in bombings and terrorist acts.

I am completely sure that among the 550 scientists (according to the Italian scientists' letter) who lost their jobs there might be a few innocent victims. These mistakes are unavoidable; but there are also many more who have used their public jobs for political activism. I know personally a number of scientists who in many years have not published a single paper describing their research. Apparently there was no research which suited their personal interest; only politics. During these many years the taxpayers paid their salaries.

It is not true that leftist people are being pursued in Argentina. Terrorists and guilty people, disregarding their political preferences, are being pursued. Numerous rightist members of the last government are now in jail because of mismanagement of public funds and robbery.

Because of the economic disaster produced by the previous government scientific institutions had to cancel their subscriptions to practically all scientific publications. Since I am temporarily in the USA continuing my research, I am perhaps one of the few Argentinian scientists who can read *Nature* and other publications in my field of interest. My colleagues in Argentina are not so lucky.

It is very difficult for Italian scientists to imagine the real situation in my country in all aspects (not only science) over the past four years. For that reason I understand that it must be difficult for them to state an impartial opinion taking into account all the facts. Certainly it was an incorrect evaluation by these 70 Italian scientists that led them to write their uncritical letter to *Nature.*

HUGO LEVATO

Kitt Peak National Observatory,

Alternative refrigerants

SIR,—F. A. Cotton (Correspondence, March 25, page 280) attributes to us the suggestion that, "if we do not choose to give up refrigerators, we may have to continue tolerating atmospheric pollution by chlorofluorocarbons, even if we ban aerosol cans". In fact, we made no such suggestion, as any reader can verify (Correspondence, March 4, page 8). Our letter dealt with facts only, and we suggested that any decision to ban R-12 take those facts into account.

Cotton states that "refrigerators . . . normally release their refrigerant gas only when junked". Actually, the reverse is usually true; refrigerators are junked once their moving parts are so worn that they can no longer retain the refrigerant for a reasonable length of time For this reason alone, Cotton's suggestions for laws promoting the recovery of refrigerant from refrigerators would not solve the problem of chlorofluorocarbon refrigerant release to the atmosphere.

W. J. Megaw (Correspondence, May 6, page 261) says a short release time of two years for a refrigerant is partly due to freeze drying applications and partly due to head and tail collisions of automobiles containing air conditioning systems. A Bureau of Domestic Commerce study (*Economic Significance of Fluorocarbons,* December 1975) does not identify freeze drying as a significant source of fluorocarbon emission. The one- to two-year replacement time for automobile refrigerants is again due to leakage; automobile air conditioners are of necessity light weight and are subjected to vibrations and temperature extremes of the automobile engine. Automobile air conditioners use R-12 exclusively.

The BDC study attributes R-22 as being 30% of the total refrigerant used, not 50% as Megaw states. R-22 is used primarily in building air conditioning where low temperature is not required. Commercial and home refrigerators and freezers use R-12 almost exclusively. R-12 and R-22 are not interchangeable in existing refrigeration equipment, valued at $100,000 million, because they have quite different physical properties. Total replacement of R-12 and R-22 would require redesigning many refrigeration systems. These refrigeration systems will necessarily be more expensive since they must operate at higher pressures. Difficulties posed by compressors burning out have thus far prevented the use of R-22 in refrigerators and freezers This design problem is a consequence of the high heat of compression, low density and high specific heat of R-22.

Model calculations by Sze and others indicate that an additional two years of fluorocarbon production will lead to 0 1% additional ozone reduction. This assumes an infinite troposphere lifetime for R-11 and R-12, that is, a maximum reduction in the ozone. We believe that an immediate ban on refrigerant or aerosol propellent uses of R-11 and R-12 would be unwise in view of present uncertainties in the theory. The two-year moratorium requested by industry to continue research programmes that began over a year ago, and which have already been fruitful, is very reasonable.

Assumed dipolar geomagnetic field

from Peter J. Smith

WHEN Johnson *et al.* (*Terr. Magn. atmos. Elect.*, **53**, 349, 1948) carried out their early palaeomagnetic work on recent Pacific sediments and the Holocene glacial clays of New England, they clearly saw their studies as just part of a much grander design. In respect of the wider aim their point was that "in order to determine the origin and nature of the Earth's magnetic field and to test the various hypotheses which have been advanced to explain the field, it is desirable to determine the history of this field throughout geologic time and to investigate more carefully its spatial variations, both inside and outside the Earth's surface".

As it turns out, it has been possible to make progress on the origin of the geomagnetic field largely without invoking the geological time dimension, and to this limited extent Johnson and his colleagues were mistaken. The self-exciting dynamo, the only viable field source known, may be regarded as an explanation of the present and recent fields without necessarily accepting that the details of any dynamo model applicable to today's field were valid throughout the Earth's history. Since the dynamo was discovered, detailed models have, of course, been extended to the geological time scale by the incorporation of field reversals and field intensity fluctuations, and for this and other reasons it is implicit in most modern models that the geomagnetic field has always been predominantly dipolar But there is nothing in the dynamo principle as such that would preclude higher order fields in the past; and to the extent that more than the principle is applied to past ages, the dipolar nature of the field could be said to appear as an assumption.

It also appears as an assumption in most studies involving palaeomagnetic directions. Until the 1950s, palaeomagnetists generally felt that sufficient measurements would make it possible to define the morphology of the geomagnetic field throughout much of the Earth's life, subject only to the availability of enough rocks with sufficiently stable magnetisations. But ironically they were to be thwarted in this by their greatest achievement, the quantitative proof of continental drift. Once it became clear that continents had moved, it became equally evident that no simple test for dipolarity based on a stationary frame of reference could exist beyond very strict limits. It would be impossible to separate easily the effects of definitely moving rocks from those of possibly changing field shapes.

So the dipole assumption now appears in two different situations, making it just as desirable to determine the history of the geomagnetic field as it was in the time of Johnson *et al.* But how can the dipole hypothesis be put to the test? As far as very recent times are concerned there is no problem, for movement of the reference frame resulting from drifting continents has been small and changes in palaeomagnetic pole positions on that account have been within the errors of measurement. Thus more than a decade ago, Irving (*Paleomagnetism and Its Application to Geological and Geophysical Problems*, Wiley, New York, 1964) showed that the eleven then-available poles covering approximately the past 7,000 yr were grouped around the present geographic pole, and McElhinny (*Palaeomagnetism and Plate Tectonics*, Cambridge University Press, 1973) has shown that British archaeomagnetic poles taken at 100-yr intervals from AD 1900–1000 and AD 300–100 were distributed likewise. Both results suggest that during the past few thousand years at least the geomagnetic field has been dipolar and that on average the dipole lay along the rotational axis.

In practice, this test may also be successfully extended somewhat further back in time. According to McElhinny, for example, 67 poles covering the past 5 Myr are clearly grouped around the geographic pole with a mean pole at 88.8°N, 131.9°E. Opdyke and Henry (*Earth planet. Sci. Lett.*, **6**, 139; 1969) showed that palaeomagnetic inclinations from 52 deep sea sediment cores less than 3 Myr old were in close agreement with those to be expected from an axial geocentric dipole. And Tarling (*Principles and Applications of Palaeomagnetism*, Chapman and Hall, London, 1971) has even shown that poles from igneous rocks up to 20 Myr old are grouped around the geographic pole, albeit with a greater scatter than for shorter, more recent periods.

Wilson and Ade-Hall (in *Palaeogeophysics*, Academic, New York, 1970), on the other hand, found a tendency for Quaternary and Upper Tertiary poles from individual regions to lie on their respective far sides of the geographic pole. On the face of it, this would seem to call in question the average axial nature of the dipole, although Wilson (*Geophys. J.*, **19**, 417; 1970) attributed the phenomenon to deviations from geocentricity; the axial dipole is apparently shifted northward with respect to the Earth's centre. In any event, the effect is small enough to be regarded as a second approximation. In no case is the basic dipolarity of the field in question; on the contrary, the dipole assumption is strengthened.

Beyond the Upper Tertiary, however, interference from continental movements causes difficulty. Over the longer geological period, poles of similar age from different regions of a single rigid landmass seem to be consistent with an average axial dipole, the variation of the dispersion of palaeomagnetic directions with palaeolatitude is usually comparable with that to be expected from the present dipolar field, and palaeolatitudes calculated on the axial dipole hypothesis are broadly consistent with latitude-dependent palaeoclimatic indicators. But none of these can be regarded as a rigorous test of dipolarity; the best that can probably be said is that there is little evidence actually to refute the dipole. The new test for dipolarity and its application to the Phanerozoic, reported by Evans on page 676 of this issue of *Nature*, is thus very welcome, although other tests may still be required before the persistence of the dipole can be said to be scientifically certain. ☐

Predator or prey?

Peter D. Moore

It is not unreasonable to suppose that a predator normally reduces the numbers of its prey, but there are certain exceptions to this general principle. One example emerged from the experiments of Porter (*Nature*, **244**, 179; 1973) on the grazing of zooplankton upon planktonic algae. In a small mesotrophic lake in Connecticut she enclosed water samples in 0.5 m^3 polythene bags and artificially enriched the population of zooplanktonic grazers within some of these. After four days Porter sampled the various bags and determined whether each of the phytoplanktonic taxa represented had decreased or increased in density.

Flagellates, nanoplankton and diatoms were suppressed by raised grazing pressures; desmids, dinoflagellates and chrysophytes were unaffected but, rather surprisingly, the larger green algae increased in density under more intense grazing. The unaffected groups were rarely found in the guts of the grazers; they were probably selectively avoided. The greens, particularly those species with a gelatinous sheath around their cells, were found to be viable after passing through the guts of grazing zooplankton. Porter suggested that the fragmentation of larger colonies of gelatinous greens in *Daphnia* guts could enhance population growth rates. She also considered it possible that the gelatinous sheaths could protect the cells against digestive enzymes and yet allow the cells to take up inorganic ions and small molecules even within the animal's gut.

Porter has now put these ideas to the test (*Science*, **192**, 1332; 1976) in a series of experiments involving radioactive tracers. The colonial alga *Sphaerocystis schroeteri*, which has a mucilage sheath, was fed to the grazing crustacean *Daphnia magna*, together with the desmid *Ankistrodesmus falcatus* (no mucilage sheath) which had been supplied with $NaH^{14}CO_3$ and $K_2H^{33}PO_4$. Subsequent sectioning and autoradiography of the *Daphnia* gut showed that both ^{33}P and ^{14}C had been taken up by *Sphaerocystis* from the broken cells of *Ankistrodesmus*. ^{14}C uptake was enhanced by light, suggesting that its uptake was autotrophic. Thus nutrient supply, as well as the physical dissociation of algal colonies, may contribute to the observed enhancement in population growth rate. Porter has now been able to quantify the enhancement, for in a controlled experiment, the population of algae which had passed through a *Daphnia* gut had grown by 63% in 24 h. Ungrazed populations were unchanged in the same period.

Porter points out that the mucilaginous green phytoplanktonic taxa like *Sphaerocystis* have summer rather than spring blooms. At this time free nutrients in the water are depleted and the guts of grazers provide a locally enriched microhabitat. Porter refers to the relationship as one of 'nascent symbiosis' between acquatic plants and grazing animals. But it is certainly not a mutualistic one. It is a refreshing example of an evolutionary confidence trick whereby the hunter is exploited by its supposed prey.

How closely should continents fit together?

A recent article by Hallam (*News and Views*, **262**, 94; 1976) in which my paper on global expansion and continental displacement during the Mesozoic and Cenozoic (*Phil. Trans. R. Soc.*, **A281**, 223; 1976) is reviewed, contains certain factual errors which need to be corrected. Less important is his initial statement that I have argued post-Pangaea continental displacement to be a consequence of global expansion since the early Jurassic. This is not entirely correct, and the importance of the role of convection in the asthenosphere in the production of the Earth's oceanic crust is implicit throughout the paper. The continental geological information, oceanic-floor spreading patterns and the distribution of present and former subduction zones during the last 180 Ma indicate global expansion at the rate envisaged in my paper. These data do not support the concept of an Earth of constant modern dimensions, as progressive subtraction of isochronous oceanic crustal area on such a model readily shows.

Hallam cites three examples of areas of continental crust which occur in the magnetic quiet zones, and which might affect the fit of the continents together to reform Pangaea such as that given in my maps. The paper by Jansa and Wade (*Geol. Surv. Canada Pap.*, **74–(30)2**, 51; 1975) to which he refers actually describes the submerged continental shelf off Newfoundland including Flemish Cap. It is indeed continental crust and is shown as such on my maps. The adjacent Atlantic oceanic crust with its typical seismic and magnetic characteristics is well described by Grant (*Geol Surv. Canada Pap.*, **74–30(2)**, 217; 1975) in the same volume. The magnetic quiet zone east of the Vöring Escarpment described by Talwani and Eldholm (*Bull. geol. Soc. Am.*, **83**, 3575; 1972) is also included in my maps as continental crust; the area to the west of it shows simatic crustal characteristics. The paper by Burollet and Byramjee (*Notes Mém. Comp. Fr. Pétroles*, **11**, 71; 1974) does not provide definitive evidence that widespread crustal areas off the continental shelf of Africa consists of downfaulted continental crust. The evidence available does indicate that east of the margin of the east African continental shelf, a thick sequence of sediments occurs probably extending back into the mid-Mesozoic as in the case of the eastern region of the Wharton Basin adjacent to the Australian continental shelf. The continental shelf off Tanzania shown on my maps has a sequence of sediments extending back into the Palaeozoic (Kent and Perry (*Sedimentary Basins of the African Coasts* (Edit. by Blant, G.) **2**, 113; 1973) and Kent and Tarling (*Nature*, **261**, 304; 1976)). The examples given by Hallam, therefore, cannot be considered as convincing evidence against the major geometric problems considered in my paper, and indeed, the mounting geological evidence against the triangular Tethys Ocean required by constant dimensions reconstructions cannot be ignored (and this specific problem is recognised by Burollet and Byramjee (*op. cit*)).

Hallam refers to the controversy about the original position of Madagascar in the Gondwanaland reconstructions. There is evidence that Madagascar reached its northern position relative to the eastern African margin in the early Mesozoic, having moved northward during the Palaeozoic in response to pre-Pangaea crustal movements. The evidence put forward by Flores (*Trans. geol. Soc. S. Afr.*, **73**, 1; 1970) for a position of Madagascar adjacent to South East Africa and Rhodesia—Mozambique during the deposition of the lower Karroo should be given careful consideration by workers interested in this area.

H. G. Owen

How approximate are the laws of plate tectonics?

HALLAM (*News and Views*, **262**, 94; 1976) has commented on a paper by Owen (*Phil. Trans. R. Soc.*, **A281**, 223; 1976) who put forward a case for very substantial recent expansion of the Earth. Both writers discussing this problem (and certainly the history of *G* is still a very open question, (Lewis, *Nature*, **261**, 302; 1976)) appear to base their arguments on what Hallam terms a fundamental tenet of plate tectonics, "that the amount of crust created at ocean ridges must equal the amount subducted elsewhere". This is in fact, a law of constancy of mass of both oceanic and continental crust. The purpose of this comment is to point out that such a basic tenet cannot hold exactly for a body like the Earth which is mixing as it cools. A major problem of our science today is to find out just how approximate such laws really are. It also seems that if continents are to fit like pieces of a puzzle, there must also be laws of constancy of area and shape. Again, this cannot be exact for we know that the processes which lead to separation change thickness.

While at present we certainly cannot exactly quantify major earth-shell interactions, certain facts must be considered and I would here draw attention to a few examples:

(1) The rate of delivery of potassium to the oceans by solution processes alone is about 7×10^{13} g yr^{-1}. If such a value was typical throughout Earth history, then a mass of potassium equivalent to all that present in the continents would be delivered to the oceans in about 5×10^9 yr. If we add the particulate contribution then the rate of removal of continents is much faster. As stated by Gilluly, Waters and Woodford (*Principles of Geology*, Freeman, 1975) "were the present rate of erosion for the United States maintained without further uplift or isostatic rebound, the country would be reduced to sea level in about 14 m.y."

(2) According to Sibley and Vogel (*Science*, **192**, 551; 1976) "pelagic sediments, in contrast to other sediments, are not usually recycled; most are subducted and therefore act as a geochemical sink". Assuming some truth to this statement, then, as the rate of formation of pelagic sediments with about 3% potassium is about 1 km^3 yr^{-1}, again this would subduct all continental potassium in 5×10^9 yr. The formation of such sediments involves the oceanic mixing process and a potassium atom from the Mississippi may well be subducted at the Chile–Peru trench.

(3) Low K basalt comes up and higher K spilite is subducted (Keen, *Geosci. Can.*, **2**, 36; 1975). The surface layers of the ocean floor crust appear to average about 1% potassium. While there are many uncertainties (Fyfe, *Geosci. Can.*, **3**, 82; 1976) potassium removal by way of spilite subduction seems in the same order of magnitude as that supplied to the oceans by solution.

(4) Low quartz andesites debris (graywacke) may well be subducted at appropriate sites by way of the reactions graywacke-glaucophane schist-quartz-phlogopite eclogite. We know little of this process except that we do know that graywackes are dragged to depths of at least 30 km to form glaucophane schists.

In summary, there is good evidence that the continents cycle through the oceans and back to the mantle at a rate that could change crustal balance. In the spreading process, leading edges (the Andes for example) thicken and trailing edges must suffer massive erosion, even by solution. During the motions there need be no perfect conservation of mass or shape of continental crust.

Finally, it should be noted that the present configuration of the Earth would not be stable for a cooler, mixed, body. In such an Earth, the hydrosphere would hydrate the mantle, and "continental" elements like K, Na, SiO_2, would form stable compounds like phlogopite and pyroxene in the mantle. Our crust and hydrosphere, even if subducted (Fyfe, *loc. cit.*) tend to be thrown back by thermal processes.

But if the Earth is cooling, there must be increased mantle fixation of crustal components because the Earth is mixing. If we allow that the combined influences of all the above mentioned processes, subduct the continental mass about each billion years, then we could lose 20% in 200 Myr. Perhaps the interesting fact is that the steady-state approximation of plate tectonic theory is rather good.

W. S. FYFE

Reply

HALLAM REPLIES: I AM pleased that my *News and Views* article should have provoked Fyfe into writing his interesting letter giving geochemical reasons why the 'basic tenet' that crust created equals crust destroyed cannot be exactly true. It is indeed apparent that continental crustal thickness must change when separation takes place; the remarkable fact is that computer-based 'jigsaw fits' are for the most part so accurate to a first approximation. I feel no need to make further comments but Owen's letter calls for a brief reply.

My purpose was less to review Owen's paper than to use it as an excuse to discuss some awkward anomalies in continental fits which have not been adequately acknowledged or discussed by Earth scientists. I cited the Jansa and Wade, and Talwani and Eldholm, papers as examples of detailed recent work undermining the reliability of the geometric 500 fathom fit, with the implication that the same geological situation very probably holds for similar continental margins elsewhere in the world. The African margins are a good example, and absolutely crucial to reconstructions of Pangaea and to Owen's expanding Earth hypothesis. Yet Owen makes no allowance whatever for a broad zone of attenuated and subsided crust around this continent (see, for instance, his figure 11). The Burollet and Byramjee paper does not, admittedly, provide "definitive evidence", because it is in effect a broad-ranging review, and most of the critical data is based on unpublished work by oil companies. The paper does in fact contain substantial data for the region off Angola which cannot be lightly dismissed. Furthermore, Jansa and Wade spell out very clearly, with good evidence, that the north-west African continental margin is virtually a mirror image of that off eastern Canada and the United States. As for Madagascar, it is not very helpful to cite once again the much discussed paper by Flores. His purely geological arguments for a southerly position of that island can be countered by other geological arguments for a more northerly fit. The point is that the arguments based on geological comparisons with mainland Africa have proved indecisive, and that is why the palaeomagnetic results of McElhinny and Embleton are so important.

In conclusion, I repeat that I find Owen's paper a stimulating one which deserves to be widely read, even though I am sceptical about his interpretation. If it serves to point up critical areas for further analysis it will have served a very useful purpose whatever one thinks of the conclusions.

A HALLAM

Irreproducible results

from Robert M. May

CONSIDER the following game, played with the combinatorial theorist's mythical urn containing black and white balls. Initially the urn contains only two balls, one black and one white. Choose one ball at random from the urn, note its colour, and then replace it plus a new ball of the same colour as the chosen ball. The game thus proceeds, each round consisting of the random selection of one ball from the urn and replacement of this ball together with a new ball of the same colour. After N such rounds, the urn will contain a total of $N+2$ balls.

After many rounds, the urn will contain a large number of balls. What fraction of the balls will be white? The reader is invited to pause here, and to make a determined effort to guess the answer.

The answer is that for large N the proportion of white balls will tend to converge to some limiting value, p say: but this limiting value p is equally likely to take any value between 0 and 1. That is, when I play this game my plot of the proportion of white balls in the urn as a function of the number of rounds (or, equivalently, time) will exhibit some initial wiggles, but will eventually settle to a steady flat line corresponding to, say $p=0.391..$. When you play the game you see similar initial fluctuations, which damp out as the total number of balls gets large, and your experiment will similarly settle to some steady but different value of, say, $p=0.893..$, and so on. Each run of this experiment will yield to the experimenter an illusion of determinism, as his results settle to a steady limiting value; this value is, however, a random variable, differing from one experiment to the next, and determined largely by the statistical vagaries of the first few turns.

In short, this simple game provides an example where an underlying stochastic process gives results which appear deterministic (at least to the person who witnesses but one run). It is, in a sense, the mirror image of the phenomenon I recently reviewed (*Nature*, **261**, 459–467; 1976) whereby simple deterministic processes can produce results which appear indistinguishable from random fluctuations.

The above game has been known to mathematicians for some time, and has been discussed in relation to the spread of infection (Eggenberger and Polya, *Zeit. angew. Math. Mech.*, **3**, 279–289; 1923) and to stochastic population growth (Blackwell and Kendall, *J. appl. Prob.*, **1**, 284–296; 1964), but the basic messages have tended to become buried under mathematical encrustations. Cohen (*BioScience*, **26**, 391–394; 1976), in a paper exuberantly entitled "Irreproducible Results and the Breeding of Pigs (or Nondegenerate Limit Random Variables in Biology)", has disinterred the phenomenon, and suggested that it may have widespread relevance in population biology.

Geneticists such as Robertson (*Proc. R. Soc. Lond.*, **B153**, 234–249; 1960) and Hill (*Biometrics*, **30**, 363–366; 1974) have realised that this urn-and-ball game captures some of the essential features of plant and animal breeding programmes, and that replicate lines from the same initial population can be very different in the limit they reach. Cohen suggests that similar "nondegenerate limits" may arise in many ecological contexts. For example, differences in successional sequences and in climax states in apparently similar habitats may not be due to causal differences between habtitats, but may arise as variations in an ensemble of habitats (ultimately dependent on the statistical accidents of early colonisation). Differences in "species composition on apparently similar islands may result from the operation of identical forces which produce regularity only in an ensemble of islands. Differences in the sizes of prides of lions or in the social organisation of troops of Japanese macaques may reflect the inherently but lawfully variable outcome of identical underlying forces, rather than deterministic ecological differences". Most of these suggestions have been made previously by other people, but not in so precise a form.

Turning to behaviour, Cohen suggests that it is "possible that some of the significant differences among mother–child interactions, which are obvious by the time a child reaches five years of age, are due neither to inherent differences among individuals nor to environmental differences, but to sequentially dependent random forces applying equally to all mother–infant pairs".

Cohen concludes on a metaphysical note. If we had been born in another universe which had started from exactly the same initial conditions as our present one and which had been subject to the same dynamics, would we necessarily infer the same laws of nature as we infer for this universe? The urn-and-ball game holds the suggestion that our present Universe may be an irreproducible result. □

Bibliography of plant genetic resources

DURING the replacement of traditional crops by new varieties a great deal of the potential genetic variation present in the old varieties and their wild relatives has been lost. Over the past two decades however, interest in the conservation and use of the plant genetic resources that remain has been rapidly growing. The literature on the subject has naturally grown with it, and the first extensive bibliography of work in plant genetic resources has just been produced. It has been compiled by J. G. Hawkes, J. T. Williams and Jean Hanson of the University of Birmingham and as well as covering the literature devoted specifically to crop genetic resources, there is also extensive coverage of crop origins, variation and evolution, along with appropriate references in ecology, genetics, practical agriculture, phytopathology, and entomology.

The bibliography is produced by the International Board for Plant Genetic Resources and can be obtained from FAO, Rome.

Human trypanosomiasis today

from F. E. G. Cox

TRYPANOSOMIASIS has received a considerable amount of attention recently (see *Nature*, **249**, 677; 1974; **262**, 85; 1976 and the *Pan American Health Organisation Symposium on New Approaches to American Trypanosomiasis*, 1975) and the latest number of the *Transactions of the Royal Society of Tropical Medicine and Hygiene* (**70** part 2, 1976) contains a refreshingly summarised statement of the current status of this group of diseases under the title "Trypanosomiasis Today". Missing are the results of biochemical, ultrastructural and immunological studies that have made this field so attractive to many scientists over the past few years and instead there is basic information emphasising the need for sustained effort to be applied in the field and in the pharmaceutical laboratory.

In Africa, human trypanosomiasis, or sleeping sickness, is still widespread in the tsetse fly-infested areas where it exists in the form of unstable "controlled endemicity" (de Raadt, *Trans. R. Soc. trop. Med. Hyg.*, **70**, 114; 1976) Even in West Africa where the disease is under control in many places the number of new cases is increasing by about 10 per 100,000 people and there were 2,511 recorded new cases in Africa in 1974. This is a vast improvement on the 1970 figures of 9,140 but trypanosomiasis is still prevalent and the problem of "controlled endemicity" is that the movements of individuals and populations and any decrease in control measures are likely to bring about epidemics.

It is true that without control measures the situation would be worse than it is now and some of the success is due to the introduction of the drug pentamidine in 1949. No new drugs have been developed for field use for 20 years, however, (Williamson, *op. cit.*, 117). Pentamidine is only useful during the early stages of the disease and resistance to it has been recorded. The commercial production of other useful drugs is very restricted.

The immunological control of sleeping sickness is unlikely because humans seem to be unable to mount a good immune response to natural infections and because the parasites are capable of antigenic variation (Gray, *op. cit.*, 119) so control of the tsetse fly remains the best hope for eradicating this disease. The objective of insecticide control has been to eradicate the genus *Glossina* from a particular area and ground spraying has been quite successful, for example, in Nigeria, 27,500 km^2 of riverine area have been cleared of *G. morsitans* but in its natural habitat, the savannah, this species may present a different problem (Jordan, *op. cit.*, 128). The application of insecticides from the air is a relatively recent innovation and although the results are promising it is too early to evaluate this success. Without doubt insecticides will have to be used for some time to come while the possibilities of genetic and biological control are being investigated. Jordan points out that the tsetse flies are acting as conservation agents maintaining the *status quo* in Africa. Advances in trypanosomiasis control, tsetse fly eradication and land development will have to be carried out side by side if anyone is to benefit from such schemes.

Human trypanosomiasis in South America is called Chagas' disease and 35 million people are afflicted. Control of this disease is a major problem because man shares it with 100 species of wild mammals and up to 100 species of bugs that might transmit it (Minter, *op. cit.*, 124). Vector control, either by traditional insecticides or new methods, provides no immediate hope (Lumsden, *op. cit.*, 121) nor does chemotherapy. Only eight effective substances have been developed in 66 years (Gutteridge, *op. cit.*, 123) and of these only three are undergoing extensive tests. Lampit (5-nitrofuran) may soon be generally available but it is not completely effective and may have severe side effects. Possibly immunisation may be useful in the future because the parasite that causes Chagas' disease does not undergo antigenic variation (Lumsden, *op. cit.*). Immunisation is only a remote possibility, however, but with only three companies testing compounds against Chagas' disease and with insecticides such as DDT becoming scarce and expensive the immediate prospects of eradicating the disease do not look good. The increasing scarcity and expensiveness of insecticides is also a problem in attempts to eradicate sleeping sickness in Africa. □

Spiral galaxies at Cambridge

from Vincent Icke

> About 35 astronomers interested in the structure of spiral galaxies discussed their findings and frustrations during a study week at the Institute of Astronomy, Cambridge.

SPIRAL galaxies are common, as Donald Lynden-Bell (Institute of Astronomy, Cambridge) pointed out in his introductory talk; considering the extremely slow evolution of galaxies, this implies that spiral structure in one form or another is almost as old as the Universe. To be explained are, among other things: why spirals occur in disk galaxies only; why spiral galaxies always contain interstellar gas; why any one form of spiral occurs, and why some spirals have bar-shaped inner parts. Recalling that it seems to be very difficult to stabilise a disk of stars against a bar-like gravitational instability, Lynden-Bell proposed that such a bar does, in fact, develop, and subsequently generates a spiral-shaped shock wave in the interstellar gas. After this introduction, contributions along six main routes followed.

The problem of the linear stability analysis of a differentially rotating disk of self-gravitating point particles (stars), has been haunting theorists especially after Lindblad's pathfinding attempts to explain galactic spirals as a normal mode of oscillation. Alar Toomre (Massachusetts Institute of Technology) described the analysis of a disk wherein all stars have the same mean orbital velocity. In such a disk, the random velocities of the stars as expressed in their distribution function (a solution of the Vlasov equation) assume a manageable analytic form. With his coworker Zang, Toomre discovered that v=constant disks are, surprisingly enough, stable with respect to two-armed instabilities, but, an even greater surprise, strongly unstable with respect to one-armed spiral perturbations! Quite the opposite has been found for disks where the rotation curve goes to zero in the centre, as is observed in spiral galaxies. In an impressive piece of analysis, Agris Kalnajs (Mt Stromlo and Siding Spring Observatories) concluded that this inner region of solid-body rotation (where velocity is proportional to radius) is largely responsible for the instability. The usual procedure to avoid instabilities is to reduce the effective mass of the stars, by, for example, surrounding the disk with a massive halo. Kalnajs showed that it is sufficient to introduce a 'nuclear bulge', that is, a small halo near the galactic centre where the rotation curve follows the solid-body line. A decrease of a factor of 4–5 in the growth rate of the instabilities was readily obtained in this way. Introduction of a bulge or halo effectively means the assumption of a vertical dimension in the disk, and Douglas Heggie (Royal Observatory, Edinburgh) showed that this may lead to resonant interaction between horizontal and vertical stellar motions. Approximating the stellar orbits as a three-dimensional Lissajous figure, he calculated that 1–4% of all stars may participate in resonances that bring them as far as half the disk radius out of the plane.

Linear instabilities attempt to grow indefinitely, but are ultimately stopped by non-linear effects. The analysis of these entails an awesome amount of mathematical physics, and has therefore barely begun. Elly Dekker (Sterrewacht te Leiden) described her application of quasi-linear techniques borrowed from plasma physics to the evolution of the particle distribution function in a stellar disk. Assuming that the potential can be split in a large, slowly varying, and a small, rapidly varying part, Dekker derived a diffusion equation for the evolution of the mean particle distribution. If the perturbation is stationary in a corotating frame, the diffusion coefficients depend on the contributions from the resonant stars only. She also demonstrated that the distribution function evolves so as to increase the coarse-grained entropy associated with it.

Bar-shaped distributions of stars are dynamically even more complex than disks. Some equilibrium models have been derived, and Scott Tremaine (California Institute of Technology) analysed the particular family that is obtained by squashing a homogeneous tri-axial ellipsoid along its rotation axis to zero thickness. He found that these bars are unstable if they are nearly circular or rotating very rapidly. The remaining configurations are stable, at least up to third-order harmonic deformation. Apparently, rather elongated bars can survive when rotating slowly.

Increasing computational power has facilitated numerical studies of gravitating *N*-body systems. The main problem remains the simultaneous modelling of the long and the short range forces. Special techniques are needed to approximate both close encounters and global structure in such a way as to preserve the collisionless behaviour of the system. Robert Berman (University of Reading) gave a progress report on a potential-solving technique developed by Hockney and Brownrigg for a fully three-dimensional 25,000-body system. Studies of disk-halo models with halo potentials more realistic than those hitherto used, showed that the disk can be stabilised against bar formation if the halo is only marginally more massive than the disk. Also, if bars did develop, they often showed structure in their interior, in the form of nested rings or a smaller bar.

The considerable mathematical difficulties arising in the attempt to solve the Vlasov equation naturally lead to a search for shortcuts, preferably by assuming that the system can be described as a gas or similar continuum. An especially successful dodge was employed by Jim Bardeen (University of Seattle) to determine the unstable modes of a gaseous disk. He expanded the potential to first order in the disk thickness, and wrote the resulting equations in terms of Legendre polynomials. This enabled him to reduce the stability problem to a matrix eigenvalue equation. Truncating the matrix to 96×96, a set of growing modes emerged with some interesting properties. An increase in gas pressure decreased the number of growing modes, but did not reduce their growth rates very much. The potential of the modes was not a simple multiple of their surface density, unlike the WKBJ modes studied by others. Most significantly, the modes appeared to be superpositions of short-wave partial modes travelling inwards and outwards. The flow of gas induced in the plane of a bar-like potential depression was studied by Karl-Juhan Donner (Institute of Astronomy), who followed up Lynden-Bell's earlier suggestion, and by Takuya Matsuda (University College, Cardiff), who in collaboration with Sorensen and Fujimoto employed a 50×30 point fluid-in-cell method to obtain a numerical simulation of the gas flow in a barred spiral galaxy. Matsuda showed that standing shocks develop roughly parallel to the bar, through which gas is deflected so strongly that it rapidly assembles in the galaxy's nucleus. A second pair of shocks, detached from the first set, occurred near the region where the Keplerian velocity in the galactic plane equals the rotation velocity of the bar. The behaviour of motions out of the galactic plane, induced by shocks in the disk, was calculated by Alastair Nelson (University College, Cardiff), who found that the perturbations propagated almost vertically upwards, reaching considerable amplitudes in the tenuous regions at 300 pc height.

The last word, obviously, was for the observers, who produced something like a fascinating cold shower. Renzo Sancisi (Sterrekundig Laboratorium 'Kapteyn', Groningen) produced new radio maps obtained with the Westerbork synthesis radio telescope of NGC5383, the best maps of a barred spiral obtained to date. Gas was found concentrated near the ends of the bar and especially in the nucleus. Also, a low-brightness disk extending over a diameter of fully three disk lengths was observed, which made it possible to determine the rotation curve in this region. It appears that the central parts (out to half the length of the bar) rotate like a solid body. Thereafter the rotation speed stays almost constant. The bar was also seen in 1,415 MHz continuum, and deep plates taken by Van der Kruit and Bosma show that the optical extent of the galaxy is about as large as the neutral hydrogen disk. Evidence that even nicely-looking galaxies like M81 can be involved in spectacular events was produced by Leonid Weliachew (Observatoire de Paris, Meudon) and by Geoffrey Cottrell (Mullard Radio Astronomy Observatory, Cambridge) who described observations of the region around M81, M82 and NGC3077. These are surrounded by a huge hydrogen halo, in which the velocities of the gas clouds link up nicely with those of the galaxies. Cottrell presented a computer model of a tidal encounter between M81 and NGC3077, which properly reproduced the radio appearance of the latter. Presumably the hydrogen halo consists of debris left over from an encounter between M81 and M82. Finally, it was demonstrated that many spiral galaxies are not flat at all, perhaps necessitating some drastic rethinking of extant models. Darrell Emerson summarised an observational programme of the MRAO on M33 and M31, both members of the Local Group of galaxies. The plane of M33 was known to be warped, and the new observations conclusively showed the enormous extent of these distortions, with warps rearing above the plane to heights almost equal to the galaxy's radius. In M31, the Andromeda Nebula, smaller warps were discovered at the edge of the observable radio disk (about 30 kpc radius). Then Sancisi proceeded to show that possibly all spiral galaxies are warped: four members of a nearby, but otherwise random, sample of five spirals seen almost edge-on showed up to 20% warping of their planes. Two of these have no nearby companions, so that if the warps are due to tidal distortion during an encounter between two galaxies, the distorted galaxy must maintain a rather crisp warp during 4–5 galactic years at least. This baffling finding left the participants in the discussion appropriately wondering how much progress, exactly, has been made in understanding spiral structure. □

Dynamo model of double radio sources

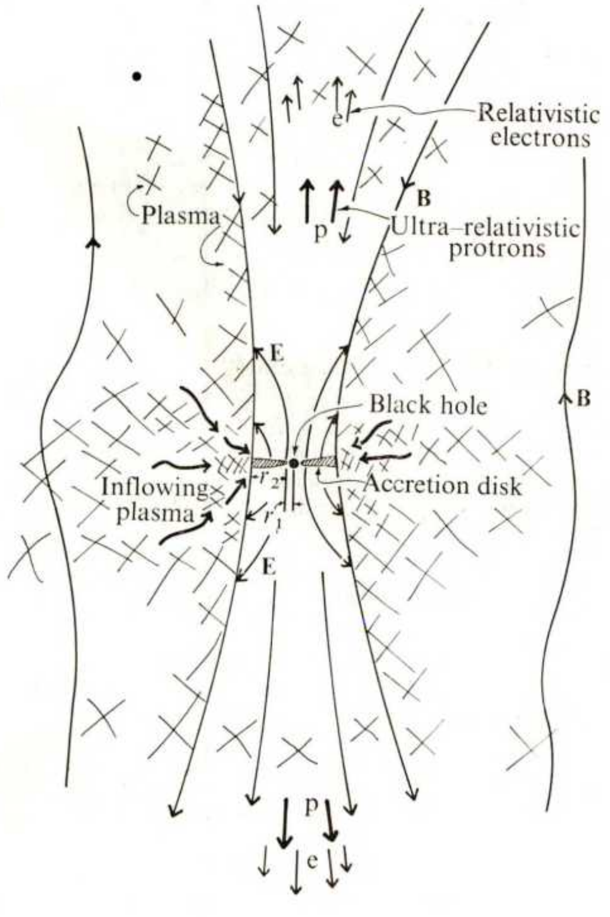
R. V. E. Lovelace

Department of Applied Physics and Laboratory of Plasma Studies, Cornell University, Ithaca, New York 14853

A model of radio sources is proposed in which the magnetised accretion disk of a massive black hole acts as an electric dynamo producing two oppositely-directed beams of ultra-relativistic particles.

WE give here a brief development of a model of double radio sources with the conducting, magnetised accretion disk of a massive black hole acting as an electric dynamo. The electric field created by the rotating disk results in the steady generation of two oppositely-directed, collimated, tenuous beams of ultra-relativistic protons. The output power in the beams is $\sim 10^{44}$ erg s^{-1} and the proton energies are $\lesssim 10^{19}$ eV for a poloidal magnetic field of the disk of 10^3 gauss and a black-hole mass of $10^8 M_\odot$. The beams propagate parallel to the angular momentum vector of the disk. The energy transported by the proton beams is gradually degraded because instabilities lead to the sharing of the beam energy with the ambient plasma. It seems possible that the two-stream interaction can convert the energy of a tenuous proton beam into a relatively dense, collimated beam of relativistic electrons. Energy carried by the electron beams is released as synchrotron radiation in the radio components.

Fig. 1 Schematic drawing of the electric dynamo formed by a conducting magnetised accretion disk. The radio wave emitting regions are discussed in the text.



With this model it seems possible (1) to have a large, steady supply of energy to widely separated small radio components, (2) to obtain alignment and symmetry of the two radio components, and (3) to have a correlation between the axis of the radio components and the direction of the angular momentum of the parent galaxy. The model includes some of the features of the 'twin exhaust' model[1], the spinar or oblique-rotator models[2-5], the magneto-hydrodynamic models[6,7] and the axisymmetric pulsar model[8]. The isotropic production of low energy ($\sim 10^{12}$ eV) cosmic rays from the accretion disk of a massive black hole has been discussed previously[9,10].

Model

Consider the possibility[9,10] that a black hole of mass M_h ($\sim 10^8 M_\odot$) has formed in the centre of a galaxy (or in the nucleus of a quasar) and that the black hole is surrounded by a massive, flat accretion disk (see Fig. 1). Gaseous material accreted on to the disk is supplied from the mass loss of stars, possibly increased by disruptive collisions between stars and/or the close approach of stars to the black hole[11]. It is evident that the angular momentum vector of the disk will have a direct correlation with the angular momentum vector of the parent galaxy. If the mass of the disk is sufficiently large, $M_d \gg M_\odot$ (but $M_d \ll M_h$), then the angular momentum of the disk may have a fixed direction in space for long periods, greater than the lifetime of a radio source. For $M_d \gg M_\odot$, the disk angular momentum corresponds to an average of the angular momenta of a large number of stars.

The magnetic field

Ionised matter moving into the accretion disk will carry with it a weak ambient magnetic field. The gradual inward radial motion of matter in the disk will amplify the field, tending to establish $B_z(r) \propto \sigma(r)$, where σ is the surface density of the disk, r is the radial distance from the black hole, and the z axis is normal to the plane of the disk. We consider that B_z at some particular epoch has a single polarity throughout the inner part of the disk. Because of differential rotation of the disk, the poloidal field (B_r, 0, B_z) is expected to be axisymmetric. It is, however, possible that the poloidal field is augmented by non-axisymmetric turbulent fluid motions[12] in the disk. Reconnection of the poloidal field lines occurs in the region $r < r_1, |z| < r_1$ (where r_1 is the inner radius of the disk) so that there is no build up of flux through the surface $r < r_1$, $z = 0$. (For the moment, consider that the space above and below the disk is a vacuum. Thus, although there may be a toroidal field (B_φ) embedded in the disk[9,10], $B_\varphi = 0$ in the space above and below the disk.)

The electric field

The material of the disk may be assumed highly conducting so that an observer in a non-rotating (inertial) reference frame sees a strong radial electric field, $E_r(r) = -[u_\varphi(r)/c]B_z(r)$, on the top and bottom surfaces of the disk, where $u_\varphi = (GM_h/r)^{\frac{1}{2}}$ is the Keplerian velocity, assumed much larger than u_r. Thus the potential difference across the disk is

$$V_{12} = -\frac{1}{c}\int_{r_1}^{r_2} \mathrm{d}r u_\varphi(r) B_z(r) \tag{1}$$

where $r^1 = 6GM_h/c^2 \simeq 10^{14}$ cm $(M_h/10^8 M_\odot)$ is the inner radius of the disk, and $r_2 \gg r_1$ is the effective outer radius where material enters the disk. If we assume $u_r(r) = \varepsilon u_\varphi(r)$, with $\varepsilon =$ a constant, $\ll 1$, then $\sigma \propto r^{-\frac{1}{2}}$. Because $B_z(r) \propto \sigma(r)$, we find

$$V_{12} \simeq -\surd(6) B_*(GM_h/c^2)\ln(r_2/r_1) \tag{2a}$$

where $B_* = \max(B_z) = B_z(r_1)$. In practical units

$$V_{12} \sim 10^{19}\left(\frac{B_*}{10^3\ \text{gauss}}\right)\left(\frac{M_h}{10^8 M_\odot}\right)\ln\left(\frac{r_2}{r_1}\right)\text{V} \tag{2b}$$

Observe that V_{12} is proportional to r_1, which is well defined, but depends only weakly on r_2.

Magnetic flux and time scales

The magnetic flux through the disk is

$$\Phi \sim 4\times 10^{31}\left(\frac{B_*}{10^3\ \text{gauss}}\right)\left(\frac{M_h}{10^8 M_\odot}\right)^2\left(\frac{r_2}{r_1}\right)^{3/2}\text{gauss cm}^2 \tag{3}$$

For $B_* = 10^3$ gauss, $M_h = 10^8 M_\odot$, and $r_2/r_1 = 10$, this flux ($\sim 10^{33}$ gauss cm^2) corresponds to an ordered field of 10^{-6} gauss spread over a region of $\sim$ 10 pc. A characteristic time scale for rapid dynamical variations of the disk is the orbital period at $r = r_1$, $T_d \simeq 5\times 10^4 (M_h/10^8 M_\odot)$ s. At the other extreme, the time scale for significant changes in the large scale magnetic field structure, once it is established, is $T_B = \mathscr{L}/R$, where $\mathscr{L}$ is the inductance and R the resistance of the configuration. We estimate that T_B is at least as long as the lifetime of the disk because of the large size and high conductivity of the disk.

Resulting particle acceleration

Consider the particle acceleration resulting from the disk potential. In the space outside the cylinder $r > r_2$, there is assumed to be plasma, possibly in turbulent motion, but not in rapid rotation. The electrical potential of this plasma may be taken to be zero. The region $r < r_2$ above and below the disk is for the moment assumed a vacuum. We consider in the present study only the case where B_z is anti-parallel to the angular momentum vector of the disk. Thus the potential on the disk surfaces, $V(r, \pm 0)$, produces a vacuum field in the space above and below the disk. That is, $\nabla^2 V = 0$, with $V(r, \pm 0)$ specified, with $V(r_2, z) = 0$, and with $V(r, |z| \gg r_2) = 0$. The potential $V(r, z)$ implies an electric field which tends to accelerate protons (and other ions) in the $+\mathbf{z}$ ($-\mathbf{z}$) direction out of the top (bottom) surface of the disk. The electric field, E, is $\sim (u_\varphi/c)Bz \lesssim 10^5$ V cm^{-1} for $B_* = 10^3$ gauss and $M_h = 10^8 M_\odot$. The electric force on a proton exceeds the gravitational attraction of the black hole by a large factor, $\sim 10^{12}$. The electric field is, however, small compared with the poloidal magnetic field, $E^2/B_z^2 \sim u_\varphi^2/c^2 \ll 1$.

The self-consistent, space-charge-limited flow of protons off the disk surface follows from general dimensional considerations (ref. 13 and E. Ott, T. Antonsen, and R. Lovelace, unpublished) in that the particle motion is extremely relativistic. If I denotes the total current of protons in, say, the $+\mathbf{z}$ direction, then

$$I = \kappa c V_{12} \tag{4a}$$

where κ is a dimensional factor which depends on the geometry through $V(r, \pm 0)$. We may assume that κ is not greatly different from unity (ref. 13 and E. Ott, T. Antonsen and R. Lovelace, unpublished). An estimate analogous to equation (4a) occurs in the axisymmetric pulsar model[8]. Using equation (2b), we rewrite equation (4a) as

$$I \sim 3\times 10^{17}\kappa\left(\frac{B_*}{10^3\ \text{gauss}}\right)\left(\frac{M_h}{10^8 M_\odot}\right)\ln\left(\frac{r_2}{r_1}\right)\text{A} \tag{4b}$$

Charge neutrality of the disk is maintained by a non-relativistic electron current in the region $r > r_2$. For $r < r_2$ and $|z| > 0$, there is a positive space–charge density J_z/c, where $J_z(r)$ is the beam current density.

The output power in the two beams is, from equations (2b) and (4b)

$$L_R \simeq 2IV_{12} \sim 10^{44}\kappa\left(\frac{B_*}{10^3\ \text{gauss}}\right)^2\left(\frac{M_h}{10^8 M_\odot}\right)^2\left[\ln\left(\frac{r_2}{r_1}\right)\right]^2 \text{erg s}^{-1} \tag{5}$$

The power in the beams derives from the infall of matter into the gravitational potential of the black hole. There is a corresponding flow of angular momentum[8] out of the disk carried by the poloidal-magnetic field and self-electric field of the beam and the beam protons. The beam emission may, however, represent only a small dynamical influence on the disk if $L_R \ll L_{\text{tot}}$, where L_{tot} is the total luminosity of the disk. In particular, an irregular magnetic field embedded in the disk may be dynamically important[9,10,14]. For comparison, the Eddington limit on the electromagnetic emissions of the disk is $L_E \sim 10^{46}(M_h/10^8 M_\odot)$ erg s^{-1}.

Evidence in support of equations (4) and (5) comes from many laboratory experiments which have demonstrated the production of high-current electron beams[15,16] ($I_e \sim 10^5$ A) and ion beams (P. Dreike, C. Eichenberger, S. Humphries, and R. Sudan, Cornell University Laboratory of Plasma Studies Report **172** (1975)) ($I_p \sim 10^4$ A) in this type of field configuration[15-18] ($E^2/B_z^2 < 1$) at low voltages ($V_{12} \lesssim 10^6$ V) with electric fields $E \lesssim 10^6$ V cm^{-1}. The observed beam particle energies are $\sim$ eV$_{12}$.

Beam energy/magnetic energy

An important dimensionless parameter for the dynamics of the beams is the ratio, denoted β, of the kinetic energy density of the beam to the energy density of the magnetic field. We first estimate $\beta = \beta_0$ near the disk, $|z| \lesssim r_2$. Note that we have a limit on the proton Lorentz factors γ from equation (2b)

$$\gamma \leqslant \gamma_0 \sim 10^{10}\left(\frac{B_*}{10^3\ \text{gauss}}\right)\left(\frac{M_h}{10^8 M_\odot}\right)\ln\left(\frac{r_2}{r_1}\right) \tag{6}$$

The spectrum of γ values as a function of r is expected to be relatively flat for $\gamma < \gamma_0$. An estimate of the beam density, n_B, follows from equation (4b)

$$n_B \sim 2\times 10^{-3}\kappa\left(\frac{r_1}{r_2}\right)^2\ln\left(\frac{r_2}{r_1}\right)\left(\frac{B_*}{10^3\ \text{gauss}}\right)\left(\frac{10^8 M_\odot}{M_h}\right)\text{cm}^{-3} \tag{7}$$

The total number of protons emitted per second is thus $\sim 4\times 10^{36}$ for $n_B = 2\times 10^{-5}$ cm^{-3}, $r_1 = 10^{14}$ cm, and $r_2/r_1 = 10$.

From equations (6) and (7), we find

$$\beta_0 = 8\pi \frac{n_B \gamma_0 m_p c^2}{B_z{}^2} \sim 0.7\kappa \left[\frac{r_1}{r_2} \ln\left(\frac{r_2}{r_1}\right)\right]^2 \qquad (8)$$

where m_p is the proton rest mass. Evidently, we have $\beta_0 \ll 1$ if $r_2 \gg r_1$. That $\beta_0 \ll 1$, is a result of the fact that $u_\varphi{}^2/c^2 \ll 1$ over most of the surface area of the disk. Thus for the proton acceleration and streaming in the vicinity of the disk, the magnetic field B_z is very strong. To a good approximation the protons follow the magnetic field lines and the configuration is force-free. (Values of β small compared with unity are known to be favourable to the magnetohydrodynamic stability of beams electrically neutralised by plasma[20].)

In the vicinity of the disk there is a small toroidal self-field B_φ from the proton beams. We estimate that

$$\frac{B_\varphi}{B_z} \simeq \frac{2I}{cr_2 B_z} \sim (\beta_0 \kappa)^{1/2}$$

is small compared with unity if $\beta_0 \ll 1$. This toroidal magnetic field counteracts the radial space-charge repulsion of the beam and thus tends to collimate the beam.

Divergence of beam

For distances $|z| \gg r_2$ above and below the disk, the proton beams diverge. The outer beam radius is approximated as $a(z) = r_2 (1 + |z|/H)$, where H is the scale height for the divergence. We assume that processes involved in the initial outward propagation of the beams give $H \gg r_2$. Because the beam particles start off following the field lines, $B_z(z) \propto [a(z)]^{-2}$. The β factor of the beam is proportional to a^2, and, therefore, we have $\beta \simeq 1$ at a distance $|z| \simeq z_* \equiv H(\beta_0)^{-\frac{1}{2}} \gg H \gg r_2$, where β_0 is given in equation (8). For distances $|z| \gg z_*$, where $\beta \gg 1$, the beam divergence comes from the ballistic motion of the protons (in the absence of instabilities). The usual adiabatic energy losses, involved, for example, in the expansion of a cloud of particles, do not occur for a particle beam in ballistic motion.

Radiation effects

In the initial outward propagation of the beam there may be significant curvature radiation. If ρ denotes the instantaneous radius of curvature of a proton trajectory, then the typical energy of the curvature photon is

$$\left(\frac{3}{2}\right)\gamma^3\left(\frac{\hbar c}{\rho}\right) \sim 3\times 10^{10}\left(\frac{\gamma}{10^{10}}\right)^3\left(\frac{10^{15}\text{cm}}{\rho}\right)\text{eV}$$

The rate at which a proton emits energy is

$$\frac{\mathrm{d}\gamma}{\mathrm{d}z} = \frac{2r_e}{3}\left(\frac{m_e}{m_p}\right)\frac{\gamma^4}{\rho^2}$$

where r_e is the classical electron radius, and m_e is the electron rest mass. Thus the path length for a proton to lose half its initial energy ($\gamma m_p c^2$) is

$$l_{\text{cur}} \sim 2 \times 10^{16}\left(\frac{10^{10}}{\gamma}\right)^3\left(\frac{\bar{\rho}}{10^{15}\text{ cm}}\right)^2 \text{cm}$$

where $\bar{\rho}$ is an average of the radius of curvature. In the initial stages of formation of a source we may have $l_{\text{cur}} \lesssim \bar{\rho} \simeq r_2$ if $B_* M_h \gtrsim 10^{11}$ gauss $M_\odot$. One effect of the curvature photons may be that of expelling matter and thus straightening the magnetic field in two conical regions of small solid angle defined by the velocity distribution of the protons at $|z| < r_2$. The effect is, however, inefficient because the production and scattering cross sections for the curvature photons interacting with electrons and protons are small ($\lesssim 2 \times 10^{-26}$ cm^2). The curvature photon production of electron–positron pairs off the magnetic field[21] is negligible.

The beam protons may interact with low energy photons[22] emitted by the accretion disk[9,10] and surrounding plasma to give pions and electron–positron pairs. The proton energy threshold for pion production is

$$\sim 10^{17}(1-\cos\Theta)^{-1}\left(\frac{1\text{ eV}}{\mathscr{E}}\right)\text{eV}$$

where Θ is the angle between the proton and photon momenta, and $\mathscr{E}$ is the average photon energy. The threshold for e^-/e^+ production is a factor 1/135 smaller. We estimate that the proton energy loss is small if

$$L_{\text{ph}} < 10^{46}\left(\frac{\mathscr{E}}{1\text{ eV}}\right)\left(\frac{R}{10^{17}\text{ cm}}\right)\text{erg s}^{-1}$$

where L_{ph} is the photon luminosity, and R is the effective radius of the photon-emitting region.

Counter flow instability

For distances $|z|$ larger than a certain value z_{neut} (discussed below), the proton beams become both charge and current neutralised by plasma in the beam channels. In the outward propagation of a beam, plasma enters the beam front, and, furthermore, plasma may leak radially into the beam channel because of instabilities (particularly for $|z| > z_*$, where $\beta > 1$). Thus the presence of free electrons on magnetic field lines connecting with the accretion disk presents the possibility of electrons counter-flowing and partially 'shorting-out' the proton accelerating potential. This shorting would result in an ohmic dissipation (and radiation) of a fraction ($\sim 1/2$) of the power $2IV_{12}$ in a small region of size $\lesssim r_2$ centred on the black hole with the remaining fraction of the power in the two proton beams. There is, however, a definite asymmetry between the proton acceleration and the counter acceleration of electrons.

Consider the two-stream interaction: let n_p denote the density of cold electrons (speeds $\ll c$) within the beam channel at some distance z. Then the dispersion relation for electrostatic waves with frequency ω and wavevector $\mathbf{k}$ is

$$0 = 1 - \frac{\omega_p{}^2}{\omega^2} - \frac{\omega_B{}^2 \psi^2}{(\omega - kv_B \cos\psi)^2} \qquad (9)$$

where $\mathbf{k}$ is at an angle ψ to the beam velocity $\mathbf{v}_B$, with $\gamma^{-1} \ll \psi \ll 1$, and where $\omega_p = (4\pi e^2 n_p/m_e)^{\frac{1}{2}}$, $\omega_B = (4\pi e^2 n_B/\gamma m_p)^{\frac{1}{2}}$, $k = |\mathbf{k}|$, and $v_B = |\mathbf{v}_B| = c(1 - 1/2\gamma^2)$ is the local proton speed. It is evident from equation (9) that the proton beam may be considered weak in the limit where $n_p \gg (m_e/\gamma m_p) n_B \psi^2$. In this limit a simple form of the two-stream instability occurs[23]. The frequency of the unstable wave is written as $\omega = \omega_p + \delta$, with $|\delta| \ll \omega_p$, and $k = \omega_p (v_B \cos\psi)^{-1}$ so that

$$\text{Im}(\delta) = \frac{\sqrt{3}}{2}\left(\frac{\omega_B{}^2 \omega_p}{2}\right)^{1/3} (\psi)^{2/3}$$

or

$$\text{Im}(\delta) \sim 3 \times 10^{-5}\left(\frac{10^{10}}{\gamma}\right)^{1/3}\left(\frac{pc}{a}\right)^{2/3}\left(\frac{n_p}{10^{-3}\text{ cm}^{-3}}\right)^{1/6} \psi^{2/3}\,\text{s}^{-1} \qquad (10)$$

where we have taken

$$n_B = 10^{-12}\left(\frac{pc}{a(z)}\right)^2 \text{cm}^{-3}$$

with $a(z)$ the beam radius. The characteristic wavelength of the unstable wave is

$$\lambda \simeq \frac{2\pi c}{\omega_p} \sim 10^8\,\mathrm{cm}\left(\frac{10^{-3}\,\mathrm{cm}^{-3}}{n_p}\right)^{1/2}$$

The phase velocity of the unstable wave

$$v_\varphi = c\left[1-\frac{\psi^2}{2}-\tfrac{1}{2}\left(\frac{\omega_B{}^2\psi^2}{2\omega_p{}^2}\right)^{1/3}\right] < v_B \tag{11}$$

is quite close to the speed of light. As an illustration of equation (10), for $a = 10^{-2}$ pc ($=3\times10^{16}$ cm), $\gamma = 10^{10}$ and $n_p = 10^{-3}$ cm^{-3}, an e-folding of a wave with $\psi = 10^{-3}$ occurs over a distance of $\sim 10^{-3}$ pc ($=3\times10^{15}$ cm). Thus an unstable wave may grow considerably before it convects out of the beam channel.

Because of the two-stream instability, plasma waves of finite but small amplitude are expected to coexist with the plasma in the beam channel[24,25]. One important effect of the waves is to produce an anomalous electrical resistivity (which does not depend on binary collisions). This resistivity acts to prevent electrons from partially shorting the proton accelerating potential. A self-consistent, non-linear theory of the interaction would determine the neutralisation length z_{neut}. It is of course possible that the nonlinear theory would allow only a quasi-periodic acceleration[21] of protons with a time scale $\sim z_{\mathrm{neut}}/c$.

Linear instability of the proton beams may also involve the circularly polarised Alfvén and/or cyclotron plasma waves propagating parallel to the magnetic field. The interaction of streaming cosmic rays with Alfvén waves has been studied[26,27], but apparently only under conditions where the cosmic rays are nearly isotropic.

For distances $|z| > z_{\mathrm{neut}}$, the magnetic field is the 'stretched-out' poloidal field of the accretion disk, and is nearly parallel to the local proton velocity. For example, if the magnetic flux through the disk is 10^{33} gauss cm^2 (from equation (3)) then

$$B_z \sim 10^{-4}\left[\frac{pc}{a(z)}\right]^2 \text{gauss} \tag{12}$$

where $a(z)$ is the beam radius. The proton gyro-radii implied by equation (12) are $\simeq 10^2\,pc\,\sin(\theta)\,(\gamma/10^{10})(a/pc)^2$, where $\theta \ll 1$ is the pitch angle.

The electron beams

It is possible that the energy loss per unit distance of the proton beam is determined by the two-stream interaction. A small fraction of the cold electrons in the beam channel get trapped and untrapped in the unstable plasma waves and are thereby accelerated to relativistic energies[24,25]. At the same time the proton spectrum is shifted to lower energies. A nonlinear theory is required to predict the energy spectra of the electrons and protons. It is, however, relevant that equation (11) implies that an electron trapped with the phase velocity of an unstable plasma wave has a Lorentz factor

$$\gamma_w = \Gamma(\psi^{2/3}+\Gamma^2\psi^2)^{-1/2}$$

$$\Gamma \equiv 2^{1/6}\left(\frac{\omega_p}{\omega_B}\right)^{1/3} \sim 5\times10^3\left(\frac{n_p}{10^{-3}\,\mathrm{cm}^{-3}}\right)^{1/6}\left(\frac{\gamma}{10^{10}}\right)^{1/6}\left(\frac{a}{pc}\right)^{1/3} \tag{13}$$

where we have taken $n_B = 10^{-12}(pc/a)^2$ cm. The energetic electrons are collimated with the proton beams, having small pitch angles and small synchrotron losses. An upper limit on the range of electron Lorentz factors may however occur because the pitch angles are not negligibly small. For small pitch angles the synchrotron radiation is collimated with the proton beams.

The radio components

The collimated propagation of the oppositely travelling beams of electrons terminates in two regions of size a_R at $z = \pm z_R$, which are the radio components. In these regions the magnetic field of the beam channel connects with a non-uniform irregular field. Thus relativistic electrons arriving at $\pm z_R$ rapidly lose their energy by incoherent synchrotron emission. The collimated propagation of protons with gyro-radii $\gg a_R$ continues beyond z_R, and these protons may continue to accelerate cold electrons by the two-stream interaction. The observed values of z_R extend from <1 pc to ~ 1 Mpc. Consider first the small sources with, say, $z_R < 10^2$ pc. The magnetic field is that carried by the beam (equation (12)). The momentum of the beam electrons corresponds to a pressure $\lesssim P_R \equiv (L_R/\pi c)\,[a(z)]^{-2}$, where L_R is given by equation (5). The electron pressure compresses the external medium and gives rise to shock wave structures[28,1] at $z = \pm z_R$. These structures may move with relativistic velocities in the $\pm z$ directions if $P_R > n_{\mathrm{ext}}\, m_p\, c^2$, or $L_R > 10^{42}\,(a/pc)^2\,(n_{\mathrm{ext}}/10^{-3}\,\mathrm{cm}^{-3})$ erg s^{-1}, where n_{ext} is the ambient density of the external medium. For the extended sources with $z_R > 10^2$ pc, the location of the shock structures (and associated radio emitting regions) is determined by the pressure balance conditions[28,1] $P_R \gtrsim n_{\mathrm{ext}} m_p U_z{}^2$, where U_z ($<c$) is the velocity of the structures in the $\pm z$ directions into the external medium. For the large sources, the magnetic field carried by the beam is exceedingly weak. Amplification of the field may, however, occur by field line stretching at the expense of the energy of the turbulent motions of the plasma and relativistic electrons. Subsequent to the formation of an extended double source, a second pair of oppositely travelling shock wave structures may be generated, for example, by an instability involving the accretion disk. The secondary shock structures will be aligned with the disk angular momentum and thus approximately aligned with the extended double.

The high energy protons which reach the large radio components escape into extragalactic space without appreciable synchrotron losses if the magnetic field strengths are $<10^{-3}$ gauss. It appears possible that the accumulation over time of the high energy protons lost from nearby ($\lesssim 300$ Mpc) dynamo sources has produced the high-energy end (10^{16}–10^{20} eV) of the observed cosmic ray spectrum.

An analytic solution to the electrodynamics of a magnetised accretion disk has recently come to our attention[29].

Actual and anticipated petrographic effects of carbonate undersaturation in shallow seawater

E. T. Alexandersson

Section for Sedimentology, Palaeontological Institute, S-751 22 Uppsala, Sweden

In the near future, atmospheric carbon dioxide from the combustion of fossil fuels may cause the surface layers of the ocean to become generally undersaturated with calcium carbonate. The hypothetic sedimentary effects of such an event are here discussed in the light of studies in the Skagerrak Bay, North Sea. In this area, nearshore sediments in the depth range 0–40 m are affected by present-day carbonate dissolution. Not surprisingly, evidence of inorganic carbonate precipitation is absent. Stages in the dissolution process are microscopic etch patterns on calcareous grains, partially dissolved grains, and finally structural breakdown and complete dissolution of skeletal elements. Mineral phases affected are calcite, aragonite, and a spectrum of magnesian calcites. Dissolution is quantitatively unimportant in living calcareous organisms, but preservation of shells and skeletons as fossils is much impeded. A future change towards similar conditions in all the world's shelf seas would certainly mean an end to the typical warm-sea carbonate sedimentation as it is known today on the Bahama Banks and in other supersaturated regions.

IT is a serious possibility that the industrial production of atmospheric carbon dioxide will cause the surface layers of the sea to become generally undersaturated with calcium carbonate—perhaps within no more than 30 yr (refs 1–6). If indeed this prospect is true—the hypothesis has its opponents[7]—it will have radical consequences for carbonate sedimentation in the world's shelf seas which are now mainly supersaturated. I attempt to show here that the diagenetic processes affecting carbonate sediments in undersaturated waters are in striking contrast to what is known from warm, carbonate-supersaturated regions. Should carbonate diagenesis of the undersaturation model indeed become universal in the world's shallow seas by the turn of the century, the event would certainly mean an end to the typical warm-sea carbonate sedimentation as we know it today. Carbonate sedimentation in cold, high-latitude seas would become still more restricted. A change of this nature would leave an extensive mark of lasting geological significance in the shelf sediments, well worthy of its own footnote in the history of man's influence on the natural environment.

I can take no stand for or against the probability of a future carbonate undersaturation in the surface layers of the sea. Others are conducting that debate[1–7]. My intention is to point out some of the effects such an event might have on existing carbonate sediments and related organisms in shallow waters—if ever it does occur.

My story is based on factual observations in the present-day sea. Contrary to common belief, areas with carbonate-undersaturated shallow marine waters actually exist at the present time, and they seem to be the result of natural—as contrasted to man-made—environmental conditions. Such is the case, for example, in the Skagerrak Bay in the North Sea, where the petrographic effects of carbonate undersaturation are very prominent in nearshore sediments in the depth interval 0–40 m (refs 8–10).

Knowledge in this particular field of marine carbonate sedimentation is still fragmentary, and this account can touch only on two basic aspects of the problem: first, the evidence of marine carbonate undersaturation, and second, the most obvious effects of carbonate dissolution in nearshore sediments and related organisms.

Petrographic saturometry

No one really knows the precise level of carbonate saturation in the sea, and estimates vary considerably, both of the undersaturation in the deep sea[11–13], and of the supersaturation in surface waters[14–16]. The disagreement on this point need not concern us here, however, since undersaturation in natural sedimentary environments can be diagnosed by a direct petrographic approach. The most explicit evidence of marine carbonate undersaturation is obviously the condition that carbonate sediments dissolve. During the Challenger expedition—which ended on May 24 exactly 100 yr ago—the realisation that foraminiferal ooze dissolves at depth meant the original discovery of marine carbonate undersaturation (ref. 17). Today, dissolution can be petrographically diagnosed in exceedingly small samples, even in individual sediment grains, by means of scanning electron microscopy (SEM), and one is motivated to speak of petrographic saturometry. The method is sensitive only to such levels of undersaturation that actually lead to dissolution, and hence is well suited for field studies of carbonate diagenesis. The primary diagnostic criteria are microscopic etch patterns which develop on the surfaces of sediment grains as soon as these are affected by dissolution[8]. Each kind of calcareous grain—a mollusc shell, a barnacle plate, an echinoid stereome—has its own distinctive etch pattern which is related to the mineralogy and structure of the grain fabric (Fig. 1). The SEM analyses allow identification of separate mineral species in the grains, and the degree of undersaturation thus can be related to the solubility of the various minerals, and even to different phases of the same mineral[8–10].

Petrographic saturometry in natural sediments has its limitations, however. Most important here is that etch patterns may either reflect uninterrupted dissolution in continual undersaturation, or they may be cumulative records of several dissolution events, representing occasional drops of the saturation level in an otherwise saturated, or even supersaturated, environment.

In the Skagerrak—as in other high-latitude shelf seas—seasonal fluctuations in carbonate saturation seem very likely. Three factors contribute to lower saturation levels

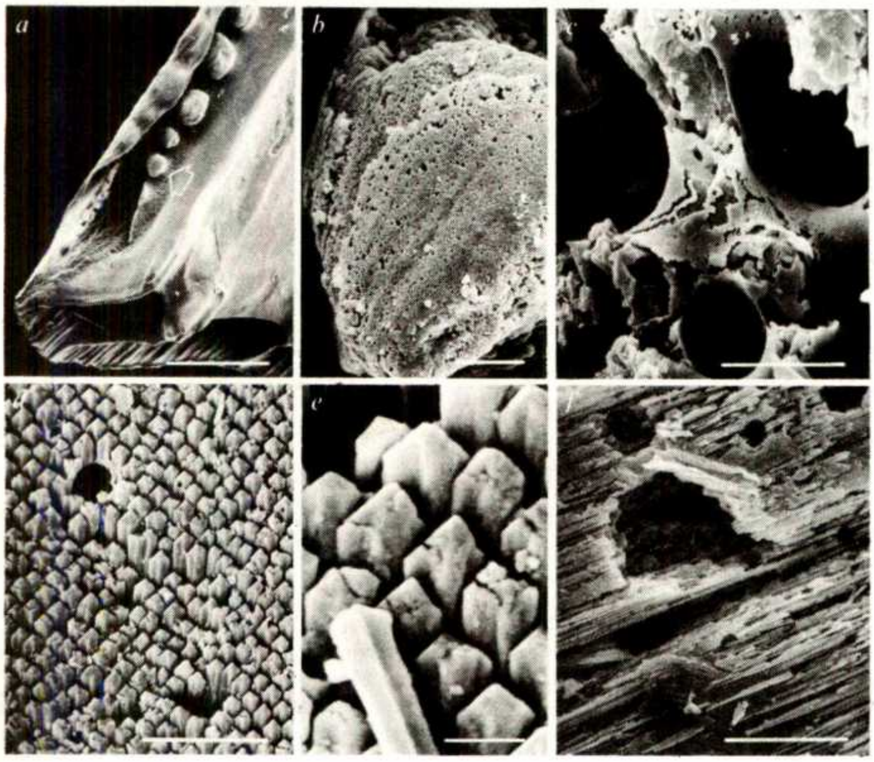

Fig. 1 Dissolution features in carbonate sediments from the Skagerrak: SEM micrographs, scale bars 10 µm, except for (*a*) 250 µm, and (*e*) 2 µm. *a*, Plate of dead barnacle collected *in situ* on rock face at 4-m depth. The entire shell was weak and crumbly. Arrow points to hinge tooth shown in detail. *b*, Corroded appearance of the calcite fabric in barnacle hinge tooth. *c*, Echinoderm fragment of magnesian calcite, grain size fraction 125–250 µm, water depth 12 m. Echinoderm fragments behave as single calcite crystals in the petrographic light microscope, but reveal an intricate core-and-rind structure during natural dissolution. *d*, Etch pattern exposing the tips of prismatic calcite fibres in *Mytilus* fragment. Grain size fraction 250–500 µm, water depth 12 m. *e*, Tips of etched *Mytilus* fibres. *f*, Transverse fracture through cross-lamellar aragonite in bivalve shell, showing partial dissolution of the fabric. The holes are corroded borings after endolithic organisms. Grain size 4 mm, water depth 6 m.

during the winters: first, photosynthesis is at its minimum so organic uptake of CO_2 is small; second, water temperatures are low so solubility of CO_2 is high and third, large amounts of CO_2 are released in the water through the decay of the summer crop of organisms.

Carbonate diagenesis in the Skagerrak

Even a cursory examination of the processes in the Skagerrak will show the fundamental differences between the carbonate-supersaturation diagenetic model so well known from warm shallow seas (refs 18, 19), and the undersaturation model in these cooler waters. The effects of a universal change to carbonate-undersaturated conditions may then be more properly assessed.

In the depth interval studied (0–40 m), the carbonates derive mainly from macroscopic benthic organisms, such as, bivalves, gastropods, barnacles, echinoderms and calcareous algae. Benthic foraminifers are of local importance. The most common single constituent is the blue mussel *Mytilus edulis* whose shell fragments give many sands a bluish tinge.

The sediments studied are nearshore sands of varying carbonate content, from a few % by weight in terrigenous sands, to > 90% by weight in skeletal sands. The grain size ranges from several cm in complete shells, to a few μm in the most comminuted material, with the median value commonly in the 200–800-μm interval.

From a mineralogical point of view, the carbonate fraction consists of aragonite, calcite, and a spectrum of magnesian calcites (Fig. 2). The proportions of mineral species in the sediments depend on the composition of the local carbonate-producing population, but calcite is nearly always dominant.

The effects of carbonate dissolution in the sediments can be seen with a simple binocular microscope: calcareous grains have a frosted, sometimes even chalky appearance, and many grains are weak and crumbly. The frosted texture is caused by surface etch patterns, whereas the chalky and powdery state originates from partial dissolution of the grain fabric.

In the Skagerrak, etch patterns occur on all kinds of calcareous grains, and it is clear that the environment is undersaturated with respect to all carbonate phases present: calcite, aragonite, and magnesian calcites[8–10]. In principle, the solubility of the carbonates varies according to the following pattern: most soluble among the sediment constituents are magnesian calcites with $\gtrsim$ 15 mol % $MgCO_3$ in solid solution; next come aragonite and the intermediate magnesian calcites, whereas pure calcite is the least soluble[20–22]. It is, however, a complicating factor that biogenic carbonate grains are intricate constructions of organic matrices and mineral substance, with the mineral part organised in various submicroscopic units of calcification. Within a single grain, the skeletal units may vary considerably in solubility because of variations in mineralogy and composition[23–25].

The heterogeneous nature of the skeletal grains determines their dissolution behaviour. Minor spatial variations in solubility in the particle fabrics control the etch topography which develops as soon as dissolution begins (Fig. 1). On continued exposure, deeper parts of the grains are gradually affected and the intragranular fabrics are partially dissolved. The process produces the familiar chalky appearance of many skeletal grains[8]. An instructive example is the cross-lamellar arogonite fabric in mollusc shells: some lamellae are selectively dissolved out of the shells while other lamellae remain as a residual chalky fabric (Fig. 1*f*).

This mechanism suggests that the rate of dissolution is slow so that the ambient undersaturation is not fully compensated by dissolution at the grain surface but exists as an undersaturation gradient some distance into the grain. The depth of the zone thus affected by intragranular dissolution is several hundred μm, and skeletal grains of medium sand size and finer may be affected by dissolution right through the particle fabric.

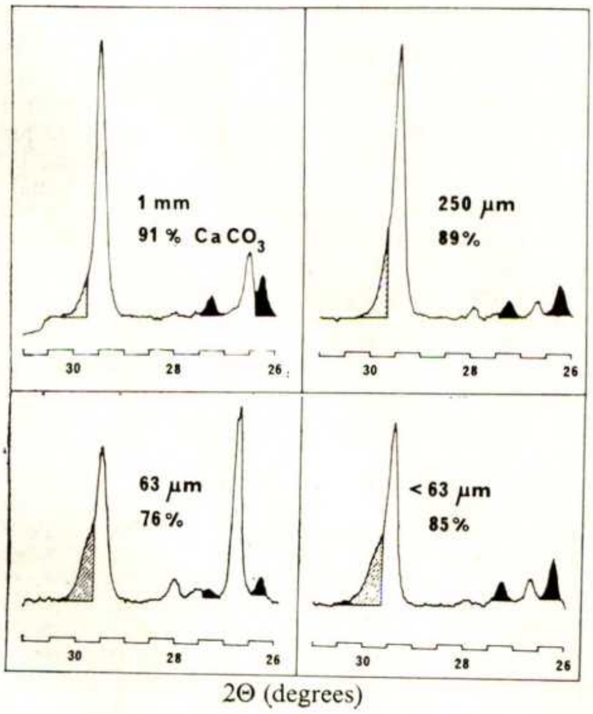
An interesting aspect of the degradation of skeletal carbonates in the Skagerrak is the decomposition of intraskeletal organic substances. The decomposition contributes heavily to the structural breakdown of skeletal grains, and the process is particularly evident in mollusc shells. In these, decomposition affects, for example, the organic sheets between layers of aragonite nacre and the sheaths around the calcite fibres in *Mytilus* shells. The aragonite nacre peels off in thin flakes, whereas the prismatic calcite disaggregates to free fibres, and both components last on their own for some time. Aragonite flakes and *Mytilus* fibres are the dominating constituents in a subordinate 'lime mud' fraction which is the final stage before complete dissolution (Fig. 3). A similar disaggregation of mollusc shells or other animal carbonates is not known from warm, carbonate-supersaturated waters, but why this is so is not understood—particularly not in the light of the abundant evidence of disaggregation of calcareous plant tissue. Recent studies indicate that the disaggregation of calcareous algae is the main producer of lime muds in warm shallow environments[26].

The Skagerrak sediments differ from warm-sea carbonate sands, not only by having a specific set of dissolution features which are unknown in carbonate-supersaturated areas, but also by lacking the various signs of precipitation which accompany supersaturation. The relationship between supersaturation and precipitation in seawater is in itself a complex problem[22,27], and it seems that the ordinary carbonate supersaturation in warm surface waters leaves a rather erratic petrographic record in the sediments[10,18,19]. Sand constituents commonly attributed to precipitation are ooids, grapestones, cemented pellets, and cements in micrite envelopes and hollow grains[18,19,28,29]. As might be expected, such constituents do not occur in the Skagerrak carbonates.

The only carbonate cements observed are all small amounts of internal aragonite and Mg-calcite cement, formed within coralline algal nodules and crusts through the calcifying processes of the red algae[30]. This biogenic cement is totally dependent on the algal life processes, and after death of the algae both skeletons and cement are attacked by dissolution.

The picture emerging from the petrographic studies of carbonate diagenesis in the Skagerrak is very consistent. It shows the absence of carbonate precipitation related to ambient supersaturation, and instead the presence of carbonate dissolution because of ambient undersaturation.

Fig. 2 X-ray powder diffractograms of various size fractions in a calcareous sand taken with Ni-filtered Cu-radiation. The black peaks at 26 and 27 are aragonite, the broad peak at 29–30 is calcite with the Mg-calcite area hatched. Relative amounts of the minerals can be calculated from peak areas (ref. 19). The relative amounts of Mg-calcite and aragonite increase with decreasing grain size, indicating a more rapid structural breakdown of these constituents.



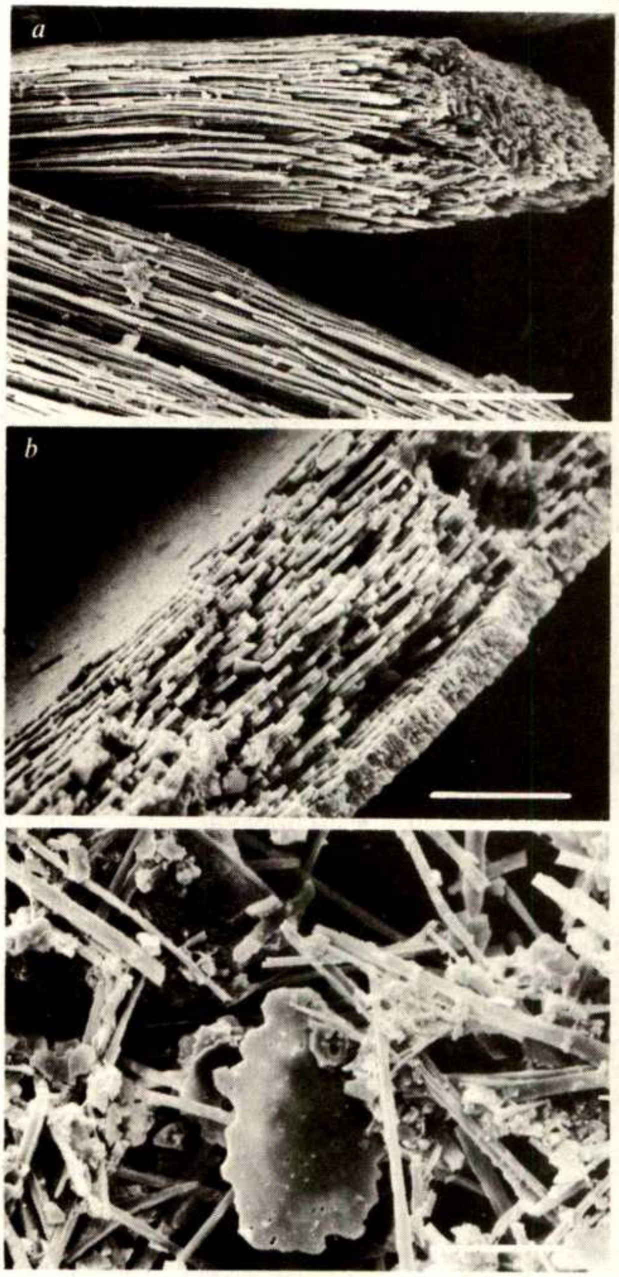


Fig. 3 Structural breakdown of skeletal carbonates in the Skagerrak: SEM micrographs, scale bars in (*a*) 50 µm, in (*b, c*) 20 µm. *a*, *Mytilus* fragments in their natural state. The calcite part of the shells is reduced to bundles of weakly coherent elastic fibres which easily disaggregate to free fibres. Grain size fraction 125–250 µm, water depth 12 m. *b*, Transverse fracture through bivalve shell with layers of peeling aragonite nacre. Grain size 1 mm, water depth 6 m. *c*, Molluscan aragonite flakes and *Mytilus* fibres in a 'lime mud' fraction of skeletal debris. Grain size fraction < 63 µm, water depth 15 m.

Is the dissolution really caused by ambient carbonate undersaturation in the seawater? Considering the various processes of organic decay that must occur in the sediments —especially when the summer crop of organisms dies off in response to the harsh winter conditions—is it not more likely that dissolution is an interstitial process at some depth in the sediments? This question was studied by monitoring the breakdown of calcareous epibionts on submarine rock surfaces away from the sediments, collecting skeletal material during SCUBA dives every fourth month. The results show that dead epibionts, such as coralline algal crusts, barnacle cups, and serpulid tubes, are attacked by dissolution while still in growth positions on naked rock-faces. The barnacle plate in Fig. 1 is an example of this. To a diver, accustomed to cuts and scratches from barnacles on rocky shores, it was a surprise sometimes to find as much as one third of a barnacle colony as friable cups which could be crushed with the tip of a finger.

The impression is that isolated calcareous organisms, freely exposed to circulating seawater on stones and rocks, are more rapidly destroyed than organisms and carbonate grains within calcareous sands. Dead calcareous epibionts disappear from their growth sites in a year or two, partly because of decomposition of the binding organic substances, and partly because of carbonate dissolution. For example, *Mytilus* shells fall off and go into the sediments because of organic decomposition, as do barnacle cups with the exception of the basal plates. Barnacle basal plates, crustose coralline algae, and serpulid worm tubes are firmly cemented to the rocks and provide good examples of dissolution *in situ*. It is worth noting that calcareous crusts do not accumulate on rock surfaces in the area, even if growth of encrusters is vigorous—a marked contrast to the conditions in many warm, supersaturated seas.

In living organisms, susceptibility to carbonate dissolution varies widely among different groups. The decisive factor is the degree of organic protection of the mineral phase, and this depends on the structural organisation of the organism. In living crustose coralline algae, echinoderms, and benthic foraminifers, the skeletons are fully protected by living substance and there is no dissolution. As previously mentioned, crustose coralline algae actually control the microenvironment in their crusts to the extent that intraskeletal carbonate cement may form in spite of the ambient undersaturation[30]. More exposed to dissolution are the shells of bivalves, gastropods, and barnacles, and etch patterns have been observed, for example, on the apical ends of shells of living gastropods. Quantitatively, however, the dissolution is insignificant in these large animals, and their life processes are unaffected. The conditions may be different for microscopic organisms suspended in seawater—for example coccolithic algae—but calcareous plankton has not yet been studied from this point of view.

As constituents of calcareous sands, skeletal fragments obviously may last for a very long time. In areas of net accumulation of sediments, the grains are buried by sedimentation and are then out of reach of the marine carbonate dissolution which does not proceed far beneath the sediment–seawater interface. The destiny of an individual calcareous sediment grain depends on a complex set of processes, involving organic carbonate production, physical sedimentation processess, wave and current action, bioturbation, bioerosion, and the degree of ambient carbonate saturation. How to define a meaningful 'rate of dissolution' in these conditions, and how to calculate such a parameter, are problems which remain to be solved.

Concluding remarks

As mentioned earlier, knowledge of carbonate undersaturation in shallow seawater is still fragmentary, and the story from the Skagerrak must be left with several holes in it. Perhaps the most annoying question is: why is carbonate undersaturation in shallow seawater so little understood from a chemical point of view? To my knowledge, the consensus among chemists is that the surface layers of the sea are supersaturated throughout, although there are discussions as to the degree[6,14–16]. Part of the answer may lie in a sampling problem. Few, if any, saturation data represent the nearshore conditions in the Skagerrak, let's say in the dark and cold at four o'clock on a January morning, when the sublittoral environment is absolutely devoid of photosynthesis, but has considerable respiration and bacterial decay. Should carbonate undersaturation occur in these conditions, however, it would be faithfully recorded as dissolution features in the sediments, clearly diagnostic in petrographic analysis.

In the absence of chemical data, it cannot be determined whether carbonate undersaturation in the Skagerrak is general and permanent, or if it is limited in space and time —for example, to the bottom waters in winter. Even if we assume that undersaturation here is limited, it does not, however, invalidate the main hypothesis of this paper—namely, that a future change to general carbonate undersaturation in the ocean's surface layers would cause radical changes in carbonate sedimentation in the shelf seas. Rather on the contrary: if an extensive dissolution record like the one in the Skagerrak can be produced by fairly limited carbonate undersaturation, how severe must be the effects of a universal change.

As far as it goes, the record in the Skagerrak sediments is entirely consistent. First, there is no petrographic evidence of ambient carbonate supersaturation, as known from warm shallow seas. Second, all carbonate phases present—calcite, aragonite, and magnesian calcites—are attacked by dissolution and gradually lost from the sediments. The petrographic record of the dissolution process consists of etch patterns and partially dissolved grains. The structural breakdown of skeletal carbonates is much promoted by decomposition of intraskeletal organic substances.

A change towards similar conditions in all the world's shelf seas would mean a radical change of the present pattern of carbonate sedimentation. The changes cannot be calculated in detail, especially the net effects of dissolution. From a petrographic point of view, an early and fundamental effect would be the termination of shallow marine carbonate precipitation. This would mean an end to largely inorganic processes such as growth of ooids, and formation of cements in grapestones, micrite envelopes, pellets, hollow grains and other sand constituents: probably also to interparticle cementation in submarine sands and beachrock. The pattern of preservation of calcareous shells and skeletons would certainly change, with effects on the accumulation of fossil assemblages in the sediments.

Sedimentary changes of this nature would stand out most drastically in present areas of high carbonate supersaturation. They would mean an end to—or rather an interruption of—the typical warm-sea carbonate sedimentation as we know it from, for example, the Bahama Banks and the Persian Gulf. In geological terms, a man-made carbonate undersaturation would probably be a brief event, but it would be irrevocably recorded in the sediments and thus take its place in the general geological record with its amazing permanence. Every geologist who has studied, for example, the details of an Ordovician limestone will probably share my conviction that sedimentary changes, however subtle, in carbonate sediments have the potential to last for hundreds of millions of years. An event of man-made carbonate undersaturation in the shallow seas might indeed produce one of the most universal and permanent records of human activity ever formed on Earth.

In a shorter perspective, it is reassuring that the evidence from the Skagerrak of today indicates that carbonate undersaturation in shelf seas does not necessarily mean serious problems for the marine environment and its inhabitants.

This study was supported by grants from Magnus Bergvalls Stiftelse, and from the Swedish Natural Science Research Council. I thank Mrs Dagmar Engström and Mr Gustav Andersson for patient and competent technical assistance, and Drs Marianne Pedersén and Anna Tolstoy for help in the field.

Cellular basis for the T wave of the electrocardiogram

I. Cohen, W. Giles & D. Noble

University Laboratory of Physiology, South Parks Road, Oxford, UK

Differences in action potential duration in different regions of the mammalian ventricle are not systematically present when quiescent tissue is first stimulated, but develop rapidly during repetitive activity. The effects of ouabain and temperature suggest the involvement of the Na$^+$–K$^+$ exchange pump.

THE electrocardiogram (ECG) has proved to be a remarkably useful tool in the diagnosis and management of many types of malfunction or disease of the heart. But after nearly a century of use and refinement, and in spite of recent advances in cellular cardiac electrophysiology, certain features of the ECG are not well understood. One example is the T wave of the mammalian ECG. It is empirically described as arising from differences in action potential duration in different anatomical regions of the ventricle. Most attempts[•] to account for the T wave have utilised indirect measurements of the sequence of repolarisation in ventricular tissue. For example, detailed studies of the relative refractory period in several anatomical locations in both ventricles and on the intraventricular septum have been reported[1]. And Spach and Barr[2] have used arrays of chronically implanted electrodes simultaneously to record potential distributions in the intact dog heart during excitation and repolarisation. We have used conventional microelectrode techniques to record action potentials in isolated preparations from sheep ventricle. The results show unexpected, activity-dependent changes in action potential duration which may provide further understanding of the mechanism of the T wave.

The T wave of the mammalian ECG is synchronous with the repolarisation phase of the ventricular action potential, and is therefore thought to represent the net extracellular field produced by the spreading of the repolarisation wave throughout the ventricular myocardium. But it is somewhat surprising that the T wave is found to be positive in the same ECG leads as the R wave of the QRS complex, since this complex corresponds to depolarisation of the ventricular myocardium.

Extracellular recordings of the potentials produced by the conduction of nerve impulses produce a diphasic wave, so that, if the leads are arranged such that depolarisation corresponds to a positive extracellular wave, repolarisation is represented by a negative extracellular wave. This result is necessary if depolarisation and repolarisation propagate in the same direction.

The apparent paradox in the directionality of the T wave is usually explained by postulating that the depolarisation and repolarisiation waves in at least some parts of the ventricle travel in opposite directions, so that regions that are excited latest repolarise earliest. This explanation requires that the duration of the action potential should be greater at the point of entry of the wave (in the endocardial muscle of the septum) than at later points in the conduction pathway (for example, in the epicardial surface of the apex). Early work using extracellular electrodes provided strong evidence for this conclusion (for discussion and references see ref. 3). More recently, recordings made with intracellular microelectrodes have shown that, during normal repetitive activity, the action potential at the epicardial surface of the ventricle is shorter than that at the endocardial surface[4].

An important possible function for such a difference is that the longer action potential at early points in the conduction pathway may prevent re-excitation and re-entry. It is therefore important to attempt to determine the cellular basis for this difference. The experiments we describe here show two important results. First, the duration differences responsible for the normal T wave develop as a consequence of repetitive activity; they are not present in the first action potential of a previously quiescent ventricle. Second, the effects of repetitive activity are strongly influenced by cardiac glycosides and by temperature.

Small pieces of tissue (2–4 mm square and 1 mm thick) were dissected from two regions of sheep left ventricles—the upper part (base) of the interventricular septum and the epicardial surface of the apex. The former is endocardial and the latter is epicardial. Some theories of the T wave regard the difference in action potential duration as being primarily between endocardial and epicardial surfaces. The alternative view is that a base/apex gradient exists. The two views are not, of course, mutually exclusive. Our choice of regions allows the correlate of either kind of gradient to be detected in action potential recordings. For simplicity we refer to the two regions as 'base' and 'apex', respectively.

After a suitable period for recovery (20–30 min) action potentials from each region were recorded using conventional 3-M KCl microelectrodes. All measurements of action potential duration were made from heat-sensitive pen recordings at the point of 80% repolarisation. In contrast to recordings made on the whole heart, it is possible to remain impaled in small pieces of tissue for prolonged periods. Moreover, since the preparations are quiescent until

•

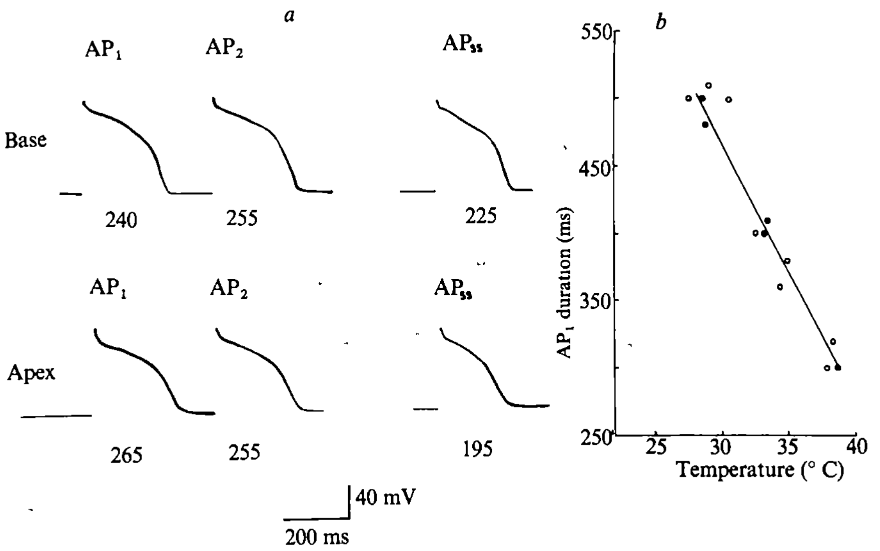

Fig. 1 *a*, Records obtained during trains of action potentials produced in base (endocardial) and apex (epicardial) preparations from sheep ventricle. Stimuli were applied at 150 per s after a 30–60-s quiescent period The time to 80% repolarisation is shown in ms below each action potential. AP_1 is the first action potential in each train, AP_2 the second and AP_{SS} is taken when there are no further changes (usually 10–20 action potentials) There is a considerable difference in the effect of activity in the two regions. At the base AP_2 lengthens and AP_{SS} is only 15 ms shorter than AP_1. At the apex AP_2 shortens and AP_{SS} is 70 ms shorter than AP_1. These particular records show a 25-ms difference between AP_1 in the two regions. This difference is in the wrong direction for explaining the normal T wave and was not found to be significant (see *b*). *b*, Duration of AP_1 as a function of temperature. There is no systematic difference between AP_1 durations at the base (●) and apex (○). Similar results were found in other experiments (although the precise functional dependence of duration on temperature was not always linear).

stimulated it is also possible to determine whether any differences that occur in the action potentials are dependent on the presence of repetitive activity.

First action potential

This question was answered by studying trains of action potentials following a short (30–60 s) period of rest. We found that there were no systematic differences between the first action potentials in the base and apex regions Moreover, this similarity between the two regions occurred at all the temperatures investigated. Figure 1*b* shows a plot of the first action potential durations obtained from the base (filled circles) and apex (open circles) between 28 and 38 °C. There is a scatter of up to about 20 ms in the durations but it is clear that the durations are not systematically different. They can be fitted by the same relationship as a function of temperature. This result was also obtained in other experiments provided that adequate time was allowed for recovery and that the results were compared from pieces of tissue taken from the same heart.

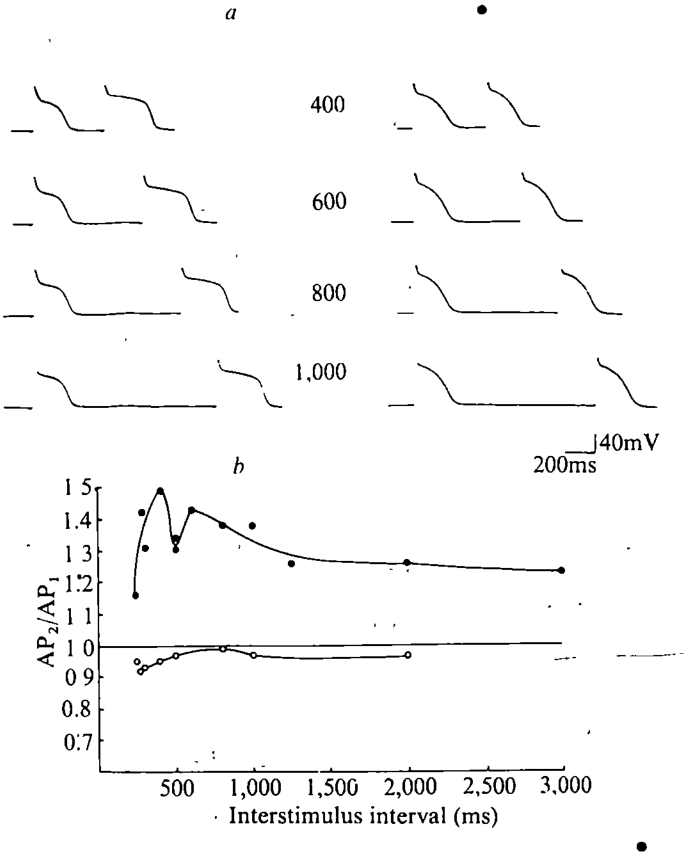
These experiments strongly suggest that there are no substantial differences between the basic ionic conductance mechanisms that control the plateau and repolarisation phases in the two regions. If such differences exist we should have to suppose both that differences in the individual conductance mechanisms are balanced to produce identical durations and that this balance is preserved for the whole temperature range. This seems very unlikely in view of the fact that the net current flow during the plateau is approximately 1% of the magnitude of the individual inward and outward currents involved[5].

Repetitive activity and second action potential

Although there are no systematic differences between the first action potential durations, it is clear from Fig. 1*a* that the effect of activity is strikingly different in the two regions. At the base we invariably found that the second action potential duration (AP_2) is substantially longer than the first (AP_1) and that the steady-state action potential (AP_{ss}) is either similar to or only slightly shorter than the first. In the case illustrated, AP_{ss} is 225 ms compared with 240 ms for AP_1. In contrast, at the apex we generally found a substantial shortening so that AP_{ss} is much shorter than AP_1. This effect is particularly striking in Fig. 1*a* since the duration of AP_1 at the apex (265 ms) is longer than at the base (240 ms). Such a difference would result in a negative T wave, as would also be the case when the durations are identical Nevertheless, in the apex AP_{ss} is 70 ms shorter than AP_1 and becomes 30 ms shorter than AP_{ss} at the base. Such a difference would lead to the positive T wave observed during normal repetitive activity. We shall discuss the results for AP_2 and AP_{ss} separately.

Twin pulse studies on sheep Purkinje fibres usually show that the second action potential shortens as the interstimulus interval is reduced. This shortening is primarily caused by residual activation of i_{x1}, the outward current which speeds repolarisation[6]. But lengthening of the second action potential has also occasionally been observed in Purkinje fibres[7]. Such experiments have shown that 10^{-6} M ouabain reduces or eliminates the increase in duration of AP_2.

Fig. 2 *a*, Records obtained during paired pulse stimulation at various intervals (indicated in ms). *b*, Duration ratios (AP_2/AP_1) as a function of interstimulus intervals from experiment illustrated in (*a*). The solid curves were drawn by eye. Note that the ratio is less than 1 at the apex (○) and substantially greater than 1 at the base (●).



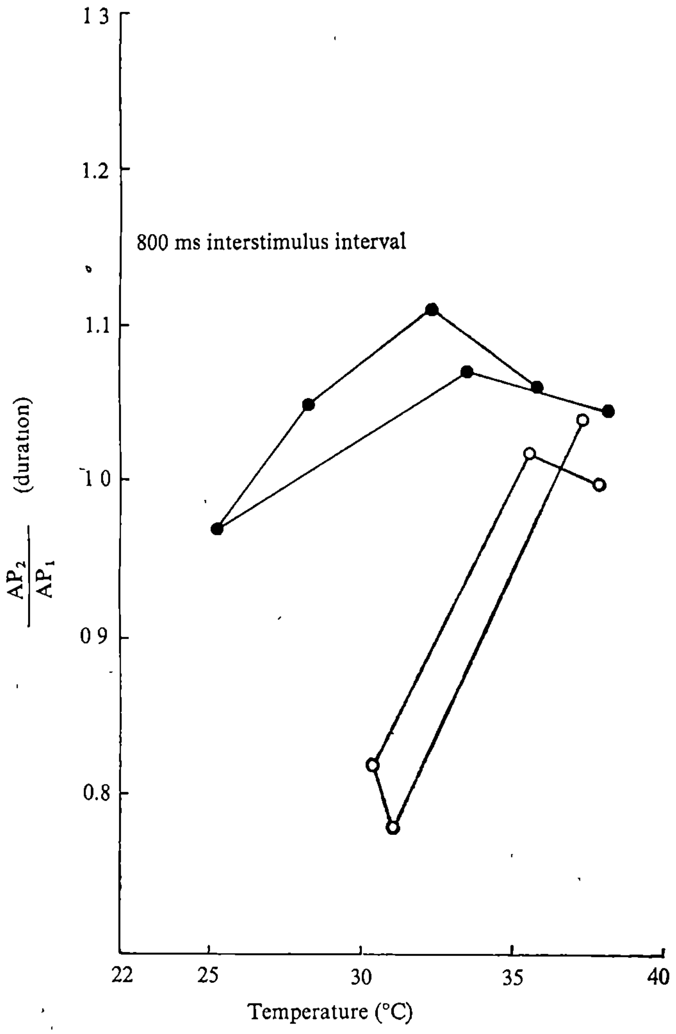


Fig. 3 Influence of temperature on the AP_2/AP_1 duration ratios at the base (●) and apex (○) at an interstimulus interval of 800 ms. Cooling has a larger influence on the apex than on the base. The effects are completely reversible in both regions.

We have studied the duration of AP_2 after application of paired stimuli at various interstimulus intervals to the base and apex regions of the ventricle. As before, a 30–60-s rest period followed each pair of stimuli. As shown in Fig. 2*a*, AP_2 at the base was substantially longer than AP_1, whereas the opposite result was obtained at the apex. Figure 2*b* shows plots of the AP_2/AP_1 ratio as a function of interstimulus interval. At all intervals, the ratio is much smaller at the apex than at the base. This result was obtained in all healthy preparations. It was important, however, to allow adequate time (about 1 h) for recovery after dissection. During recovery in apex preparations, while the resting potential was low and the first action potential was relatively short, a striking prolongation of AP_2 could be obtained. Such preparations conformed to the pattern of response shown in Fig. 2 after they reached their normal resting potential and AP_1 became normal in duration.

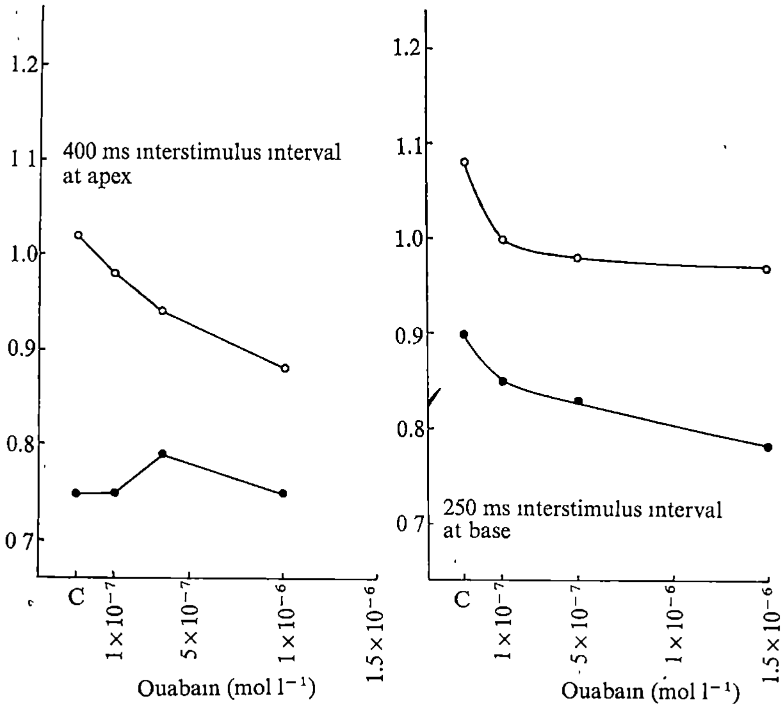
To test whether the prolongation of AP_2 at the base is attributable to the activity of the Na^+–K^+ exchange pump, we used two methods of blocking pump activity—cooling and application of ouabain. Figure 3 shows the results of cooling at an interstimulus interval of 800 ms. In both regions the AP_2/AP_1 duration ratio becomes smaller at low temperatures but the effect was always found to be more dramatic at the apex than at the base. At 38 °C the AP_2/AP_1 ratio is slightly larger than 1.0 in the apex but falls to about 0.8 when the tissue is cooled to 30 °C. By contrast, in the base, the ratio is still larger than 1.0 at that temperature and cooling to 25 °C was required to reduce the ratio significantly. These effects were totally reversible when the preparations were rewarmed.

Figure 4 shows the results of experiments on the effects of various concentrations of ouabain. In both regions, the AP_2/AP_1 ratio is significantly reduced by ouabain at concentrations that are thought to reduce the activity of the pump significantly. Unlike cooling, these effects were not reversible. This result is not surprising in view of the well known difficulty in reversing the inhibitory action of ouabain on the Na–K exchange pump.

Steady-state action potential

It is clear from the results described so far that very marked differences between the base and apex regions may develop

Fig. 4 The effects of ouabain on AP_2/AP_1 (○) and AP_{ss}/AP_1 (●) duration ratios. The stimulus frequency is 240 per s at the base and 150 per s at the apex. Further explanation in text.



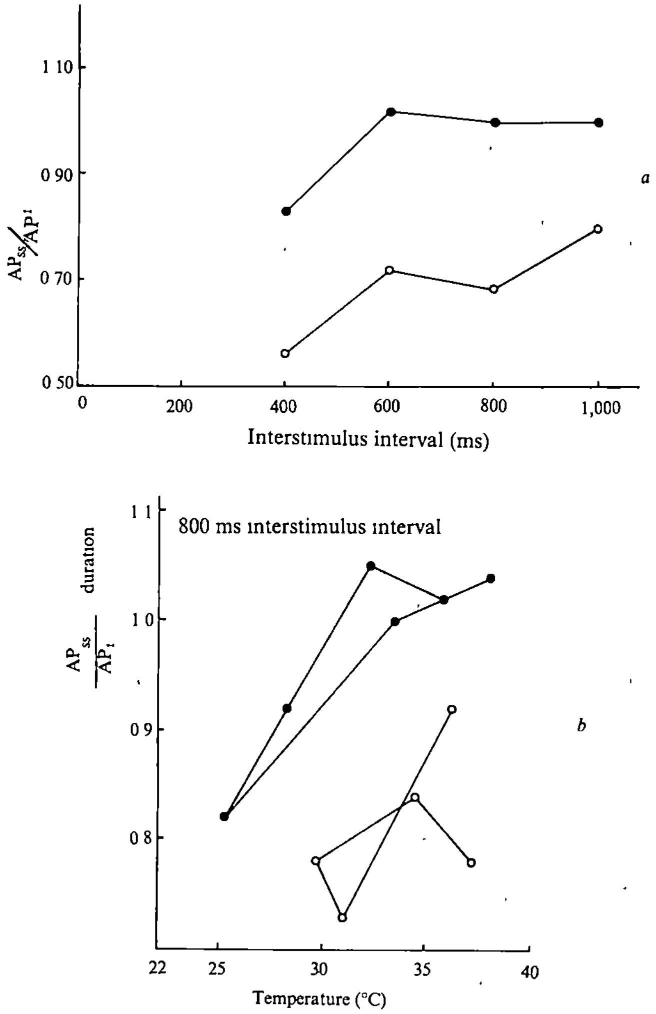


Fig. 5 *a*, AP_{ss}/AP_1 duration ratios at base (●, 38.6 °C) and apex (○, 38.0 °C) as a function of interstimulus interval. The precise influence of changes in frequency on AP_{ss} in the two regions varies somewhat between experiments but, as in this experiment, a significant difference between the two areas is found over the whole frequency range investigated. *b*, Influence of temperature on the AP_{ss}/AP_1 duration ratios in the base (●) and apex (○). These results can be compared with those for the AP_2/AP_1 ratios shown in Fig. 3. The same general phenomenon is observed, that is the apex ratio is reduced to lower levels than the base ratio by cooling. In this particular experiment, the effects were perfectly reversible at the base but not at the apex. Reversible effects on AP_{ss} were obtained in the apex in other experiments.

as a consequence of only one action potential. The difference between the durations of AP_2 in the two regions would produce a positive T wave. It is important, however, to remember that the normal T wave is determined by the steady-state action potential characteristics of maintained repetitive firing. It is therefore essential to study the durations of AP_{ss} in each region of the ventricle.

Figure 1*a* shows that AP_{ss} is longer at the base than at the apex. Figure 5*a* shows that this difference persists for a wide range of frequencies. The filled circles show the AP_{ss}/AP_1 ratio at the base as a function of interstimulus interval. The results for the apex are shown by the open circles. Although in both cases there is a tendency for the ratio to decrease at high frequencies, the difference is always substantial. This result suggests that changes in frequency *per se* should not influence the polarity of the T wave.

Figure 5*b* shows the influence of cooling on the AP_{ss}/AP_1 duration ratios. As with the results for AP_2, cooling decreases the ratio although a higher ratio is always maintained at the base than at the apex.

The influence of ouabain on the AP_{ss}/AP_1 duration ratios is shown as filled symbols in Fig. 4. The results are more difficult to interpret than those from the cooling experiments. Thus the marked shortening of the action potentials (including AP_1) produced by inhibitory doses of ouabain may give a fairly constant AP_{ss}/AP_1 duration ratio even when both AP_{ss} and AP_1 are substantially shortened. This applies to the apex results. In the case of the base, there is a decrease in the AP_{ss}/AP_1 duration ratio. This means that the AP_{ss}/AP_1 duration ratios become more similar in the presence of ouabain. If this effect is sufficiently large it could lead to a reduction or to inversion of the T wave.

Implications of the results

Several important conclusions can be drawn from our results. (1) Since the first action potentials from the base and apex are very similar in duration it is likely that the ionic currents involved are the same in the two regions. (2) It therefore follows that the differences in duration that occur during normal beating, and that are responsible for determining the polarity of the T wave, develop as a consequence of activity. The onset of this effect must be very rapid since large differences in duration are evident in the second action potential in a train. The second action potential is always longer than the first at the base. It is sometimes longer at the apex but the AP_2/AP_1 duration ratio is always greater at the base than at the apex. (3) In both base and apex regions subsequent action potentials in a train become shorter but the difference in duration between the two areas is always maintained. At normal temperatures the base AP_{ss}/AP_1 duration ratio is near unity. At the apex it is always significantly less than 1. (4) Because the prolongation of AP_2 is reduced or abolished by cooling and by inhibitory doses of ouabain it is possible that the effects are attributable to the response of the Na–K exchange pump to repetitive activity. This response, or its consequences, must be significantly different in the two regions.

Can we offer any explanation for an increase in action potential duration after increased activity of the Na–K pump? At first sight this may seem to be opposite to the expected effect since activation of outward electrogenic pumping would by itself speed repolarisation. This suggests that the effect may arise as a secondary consequence of ionic concentration changes rather than as a direct result of increased pumping. During activity, the cells will gain Na ions and lose K ions. During a single action potential the concentration changes involved will be small unless the movements occur into very restricted spaces. Narrow extracellular spaces do exist in cardiac muscle[8–10], and rapid changes in extracellular K^+ concentration may occur in them[11,12]. In particular, $[K^+]$ in the space will increase during activity. It is possible therefore that this increase in $[K^+]$ is responsible for activating the Na–K exchange pump.

It remains, however, to explain how this might prolong the action potential. If $[K^+]$ remains elevated, the action potential will shorten as a consequence of the well known effect of $[K^+]_0$ on plateau duration[13]. To obtain prolongation we would have to suppose that the pump can transiently reduce the $[K^+]$ in the small extracellular spaces or clefts to levels below normal. The action potential would then be prolonged[14].

This interpretation of our results is clearly very tentative. We have no direct evidence that cleft $[K^+]$ is reduced below normal after the first action potential. Moreover, it may be very difficult to test the idea directly as even K^+-sensitive microelectrodes are not likely to detect the $[K^+]$ level in very narrow cleft spaces. They are more likely to monitor the $[K^+]$ level in the larger extracellular spaces in the preparation.

An alternative view is to postulate that the prolongation of AP_2 is attributable to an increased inward (for example, calcium) current, which is partly (base) or completely (apex) masked by the shortening effect produced by potassium accumulation. This hypothesis leaves the mechanism of the prolongation unexplained but the difference between the base and apex regions would still be attributable to differences in the capacity of the sodium pump to respond to activity.

Whatever ionic mechanisms form the basis of the effects we have observed, our results do enable us to explain various observations on the T wave. The occurrence of myocardial ischaemia or infarction leads to inversion of the T wave, as does treatment with cardiac glycosides. We can explain these effects as a result of inhibition of the Na–K exchange pump. It is also conceivable that inversion occurs as a consequence of increasing the pump's capacity to respond so that the behaviour of the apex is made to approach that of the base, rather than the opposite. Thus, warming may allow the apex to show prolongation of the action potential during activity (Fig. 3) and so in this manner become similar to the base. This phenomenon could form the basis of T-wave inversion during fever. This possibility also serves to emphasise that it may be misleading to regard T-wave inversions as having a common cause. Any manoeuvre that leads to a decrease in the difference in AP duration will reduce or invert the T wave. This may be produced either by inhibiting the property of the basal (endocardial) region that allows unexpectedly long action potentials to occur or by stimulating the apex (epicardial) areas to respond to activity in a manner resembling that of the base.

Our results also lead to the expectation that the T-wave should be reduced or inverted after a period of quiescence. This has been observed in whole hearts of frog and tortoise after a short period of quiescence produced by vagal stimulation.

Intracellular *p*H and activation of sea urchin eggs after fertilisation

The intracellular pH of the sea urchin embryo increases 0.3 pH units between 1 and 4 min after fertilisation. The increase in pH is required for initiating development. The increase results from an exchange of extracellular Na$^+$ for intracellular H$^+$.

ACTIVATION of sea urchin eggs after fertilisation can be separated experimentally into two phases[1]. The first, which occurs in the first 60 s after insemination and includes the exocytosis of 1-μm granules in the cell cortex, seems to be initiated by an increase in intracellular free calcium[2–4]. The second, which begins 5 min after insemination and includes increased protein synthesis, commencement of DNA synthesis and other biosynthetic events, seems to result from a nonspecific and pervasive event[5]. The first phase is not a prerequisite for the second, since incubation of eggs in mM concentrations of ammonia[5,6] or treatments altering the egg surface[7,8] will start biosynthesis in the absence of the cortical granule exocytosis. This second phase of activation has been shown[9] to have an obligatory sodium requirement only during the first 5–10 min after insemination at 15 °C. If eggs are transferred to sodium-free seawater between 1 and 5 min after fertilisation, there is no activation of development; however, if sodium (>2.5 mM) is added, development resumes[9,10].

Here we present evidence that ammonia and sodium are agents in an efflux of H$^+$ ions (the 'fertilisation acid') that occurs after fertilisation. This acid represents H$^+$ ions and not a weak organic acid[11], and the result of this efflux is increased intracellular *p*H. Our data indicate that in normal fertilisation, the hydrogen efflux is mediated through a sodium–hydrogen facilitated transport system in which a transient period of sodium influx is coupled to a period of hydrogen efflux. The latter can also be induced directly by ammonia or other organic amines, in the absence of extracellular sodium. It is this hydrogen efflux, with the resultant change in intracellular *p*H, and not the sodium influx, that is the prerequisite for metabolic activation.

We suggest that the suppression of metabolism of the unfertilised egg is a result of maintaining a low intracellular *p*H and that the rapid efflux of hydrogen ions after fertilisation by way of the sodium-coupled exchange raises the intracellular *p*H. This change allows the increased metabolism referred to as egg activation.

Sodium–proton exchange

We followed acid release by measuring the extracellular *p*H of a stirred 5% suspension of *Strongylocentrotus purpuratus* eggs (17 °C), using a Corning Model 12 expanded scale *p*H meter with recorder. After acid efflux was complete, the solution has titrated back to the original *p*H with standardised sodium hydroxide to determine the amount of acid released. We used two different experimental systems for studying H$^+$ release. In the first, normal eggs were suspended in seawater and fertilised by addition of sperm or artificially activated by addition of various amines. The second system, which we refer to as 'choline-arrested eggs', is similar to that described by Chambers for demonstrating the sodium requirement for egg activation[9,10].

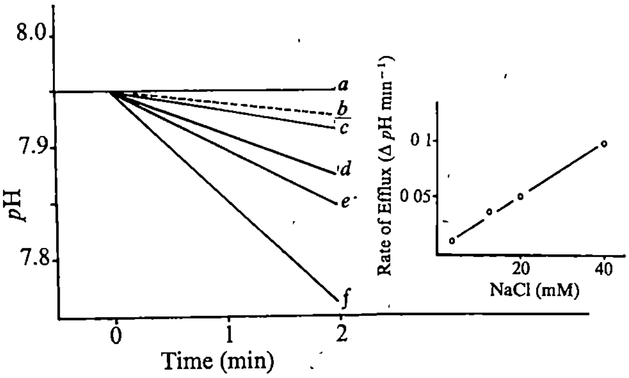

Fig. 1 Acid efflux from eggs as a function of sodium concentration (17 °C). A 2% suspension of eggs was fertilised in seawater, resuspended after 60 s in sodium-free seawater and washed twice. Sodium or lithium chloride was added, at zero time to these 'choline-arrested eggs' at the following concentrations and the initial (0–2 min) acid release measured with a Corning expanded scale *p*H meter and attached chart recorder *a*, 0.1 mM Na; *b*, 100 mM Li; *c*, 3 mM Na; *d*, 10 mM Na; *e*, 20 mM Na; *f*, 40 mM Na. Inset is the slope (rate of efflux against time) plotted against sodium chloride concentration. The relationship between *p*H and H^+ ion concentration is approximately linear over these small *p*H ranges.

Eggs were fertilised in normal seawater and then washed and resuspended in sodium-free seawater (choline substituted) 1 min after fertilisation. We then sedimented the eggs rapidly 50 s after insemination in a hand centrifuge, resuspended them in sodium-free seawater at 70 s, and then sedimented and resuspended then again in sodium-free seawater. These eggs have thus undergone a complete cortical exocytosis.

The release of protons by choline-arrested eggs can be linked directly to sodium. Varying amounts of sodium were added to choline-arrested eggs and the rates of H^+ efflux measured. The rate of H^+ efflux is linearly dependent on Na^+ concentration (Fig. 1). Although lithium replaces sodium[9,10], it is at least 50 times less effective in mediating the efflux.

To test further the nature of the sodium requirement for hydrogen ion efflux, the effects of the diuretic drug amiloride (3,5-diamino-6-chloropyrazinoyl-guanidine) were determined. This compound inhibits passive sodium transport across toad bladder membranes and has no effect on Na^+–K^+ ATPase pump[12]. Eggs were fertilised and after 1 min were transferred to the Na^+-free choline-substituted seawater. When sodium (40 mM) was added in the absence of amiloride, acid efflux was induced (Fig. 2) and the eggs were activated, as evidenced by subsequent cell division. When 40 mM NaCl was added to choline-arrested eggs in the presence of amiloride (1×10^{-4} M), no acid efflux was observed (Fig. 2); these eggs were not activated and did not divide.

Previous work in our laboratory using eggs activated by ionophore A23187 suggested that about 25% of the H^+ release is independent of sodium[13]. If this part of acid release occurs early (that is, during the first 60 s after insemination), we would not observe this Na^+-independent acid release with choline arrested eggs. We tested this possibility by fertilising eggs in the presence of 1×10^{-4} M amiloride. There was an initial phase of acid release beginning at 30 s and ending at 60 s, equivalent to 20% of the total acid; 80% of the efflux was prevented (Fig. 3). An early phase of acid efflux (30–60 s after fertilisation) thus accounts for 20% of the total hydrogen release and is independent of Na^+ and insensitive to amiloride. The second phase requires sodium and is sensitive to amiloride.

We had previously found that the various amines which activate metabolism also induce acid release (our unpublished results). The induction of acid release by ammonia (10 mM NH_4Cl, *p*H 8) is depicted in Fig. 2. The efflux is insensitive to amiloride. Similar results were obtained with procaine (10 mM, *p*H 8).

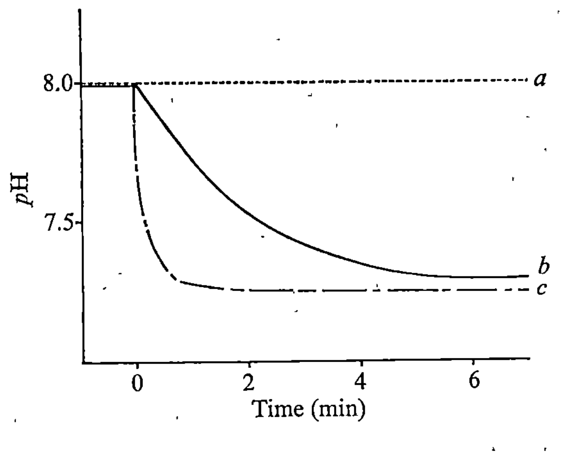
To test whether Na^+ ions are transported across the plasma membrane in exchange for H^+ ions, ^{22}Na influx and H^+ efflux were measured during the first 20 min of development. To measure ^{22}Na uptake, a 1% suspension of eggs was incubated in low-sodium seawater (choline substituted) containing 25 mM sodium and 0.75 μCi ml^{-1} of ^{22}Na. Uptake was measured for 15 min, the eggs were then fertilised and changes in sodium influx (see legend to Fig. 4) determined at 1-min intervals. ^{22}Na accumulation was first detectable 1 min after fertilisation, continued for 6 min and then levelled off (Fig. 4). The same time course is seen for acid efflux in choline-substituted seawater containing 25 mM sodium. $^{22}Na^+$ accumulation occurs only during this interval. Its termination does not result from an equilibration of internal and external ^{22}Na; when isotope was added 10 min after fertilisation in the same conditions there was minimal isotope uptake (100 c.p.m. as opposed to 5,000).

The H^+ efflux in 25 mM Na^+-seawater was measured in a separate experiment. A 1% suspension (5 ml) was fertilised and after 10 min the eggs were centrifuged and the supernatant was back-titrated to the original *p*H with standardised NaOH. The Na^+-dependent portion of the hydrogen efflux (that is, 80% of the total efflux) for 1 ml of a 1% suspension of eggs in seawater *p*H 8.0 was 4.80×10^{-8} mol and the calculated sodium influx was 4.76×10^{-8} mol. This sodium influx is in agreement with that reported by Chambers[14] and the data indicate a 1 : 1 exchange of sodium for hydrogen in these conditions.

Amiloride (1×10^{-4} M) rapidly blocked ^{22}Na uptake. When added to eggs 50 s after fertilisation, there was no ^{22}Na accumulation (Fig. 4). The 1 : 1 stoichiometry and inhibition of both acid efflux and Na^+ influx by amiloride indicates a passive, coupled facilitated transport system with the efflux of each H^+ ion coupled to the influx of a Na^+ ion.

At constant sodium concentration (0.46 M in seawater) the Na^+–H^+ exchange is dependent on external H^+ ion concentration. Confirming earlier results[11], we found that the rate and extent of acid efflux was directly related to the extracellular *p*H. Total efflux was approximately 10 μmol per ml packed cells when fertilisation was at *p*H 9 and 6 μmol ml^{-1} at *p*H 8. Below an external *p*H of 6.5 there was no detectable acid efflux and also no activation of development.

Fig. 2 Effect of amiloride on sodium-induced acid efflux from choline-arrested eggs (17 °C). A 5% suspension of choline-arrested eggs was prepared as described in the legend to Fig. 1. The *p*H of the suspension was then recorded following addition at zero time of 40 mM NaCl—— (*b*), 10 mM NH_4Cl - - - (*c*), or 40 mM NaCl with 1×10^{-4} M amiloride present - - - - - (*a*). Amiloride had no effect on acid release induced by the ammonia addition.



*p*H of cytoplasm

The observed acid efflux is quite large and should be reflected by an increased intracellular *p*H. (If the egg cytoplasm were unbuffered, addition of 6 μmol of H^+ to 1 ml of cell water at neutral *p*H would decrease the *p*H to 2.2.) An estimate of any total cytoplasmic *p*H changes was made by homogenising eggs before and after insemination and measuring the *p*H of the homogenate. A 5-ml sample of a 5% suspension of eggs was washed once in unbuffered (bicarbonate free) artificial seawater, resuspended in 5 ml of 0.5 M KCl and then disrupted with 10 strokes in a Dounce homogeniser. The *p*H was then measured immediately on the expanded scale *p*H meter with constant stirring. At an external *p*H of 8.0, the *p*H of unfertilised egg homogenates (13 separate batches of eggs) was 6.48 (±0.01) and in homogenates prepared from embryos 10 min after fertilisation (9 separate batches of eggs) was 6.76 (±0.02), a change in *p*H of 0.28.

Most of this *p*H shift can be attributed to the efflux of hydrogen ions already present in the egg, as indicated by titration experiments in which an amount of base equivalent to the released acid (0.37 μmol per 5 ml of a 5% egg suspension) was added back to homogenates of unfertilised eggs (5% egg suspension homogenised in 0.5 M KCl). The *p*H of this homogenate rose from 6.54 to 6.73, which is identical to the *p*H change seen after fertilisation. The bulk of the buffering capacity of egg homogenates is probably in small molecules, and not in heat-labile proteins. The buffering capacity of an egg homogenate that is boiled is in the 10,000*g* supernatant fluid.

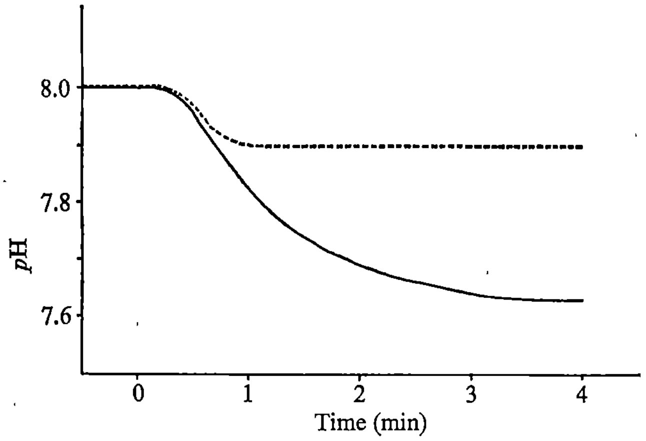


Fig. 3 Acid efflux following fertilisation of eggs in amiloride (17 °C). Eggs (2% suspension) were suspended in choline-substituted seawater containing 50 mM sodium chloride with or without 1×10^{-4} M amiloride. The eggs were then fertilised with sperm at zero time and acid release determined as described (see Fig. 1 legend). The low sodium seawater was used since amiloride is insoluble at higher sodium concentrations. Curves as in Fig. 2.

The *p*H of homogenates of fertilised eggs prepared at various times after fertilisation is shown in Fig. 5. There was an initial decrease in *p*H between 30 and 60 s, possibly related to the Na^+-insensitive phase of acid release. Then, at 1 min and continuing until 4 min, the *p*H increased to 6.74 and remained unchanged thereafter. The kinetics correspond extremely well with the time course of H^+ release in seawater.

Implications for development

As already mentioned, it has been shown previously that activation of development requires Na^+ in the extracellular environment for a 5–10 min interval after fertilisation[9,10]. Our results indicate that this Na^+ requirement for initiating development can be attributed to its effect in raising the cytoplasmic *p*H. First, the Na^+ uptake is transitory and is linked stoichiometrically to the H^+ efflux. Second, we find that activation is prevented by the concentrations of amiloride (1×10^{-4} M) which prevent Na^+ influx and H^+ efflux. This inhibition occurs only during the first 5 min after fertilisation, again corresponding to the period of Na^+ influx and H^+ efflux. Thereafter, amiloride has no effect on development (at least through first cleavage), indicating that its effects are specific to the period of Na^+ influx and not some nonspecific or toxic side effect. Third,

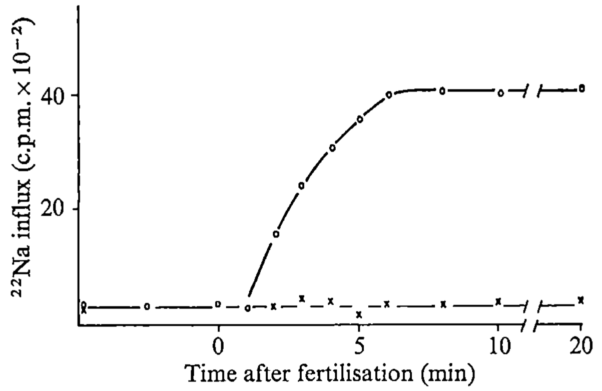

Fig. 4 ^{22}Na influx after fertilisation (17 °C). A 1% suspension of eggs was suspended in 20 ml of choline-substituted seawater containing 25 mM sodium chloride. The low sodium seawater was used because of low amiloride solubility and to increase the specific activity of the sodium isotope. ^{22}Na (15 μCi) was added 15 min before fertilisation and 2-ml samples were taken at the times indicated. These samples were added to 8 ml ice-cold seawater, quickly washed once in cold seawater, centrifuged, and 1 ml of NCS tissue solubiliser (Amersham/Searle) added to the pelleted eggs. The eggs were allowed to dissolve in NCS, transferred to a toluene-based scintillation cocktail, and then radioactivity measured in a Beckman LS-230 scintillation counter. Zero time indicates addition of sperm. ^{22}Na influx in the absence of amiloride (○) and in the presence of 10^{-4} M amiloride (×).

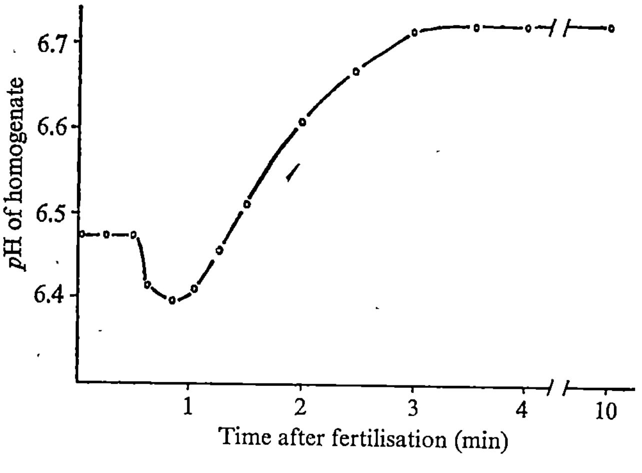
Fig. 5 *p*H of egg homogenates at various times after fertilisation. A 5% suspension of eggs was lightly treated with trypsin to prevent elevation of the fertilisation membrane and generation of the perivitelline space[20]. This was necessary to eliminate the contribution of seawater in this space to the *p*H of the homogenate. Samples (5 ml) of the trypsin-treated eggs were inseminated (17 °C) and at the times indicated, the eggs were washed once in bicarbonate-free artificial seawater, centrifuged and suspended in 5 ml of 0.5 M KCl. This fertilised egg suspension was homogenised with ten strokes of a Dounce homogeniser and the *p*H was determined immediately on a Corning expanded scale *p*H meter.



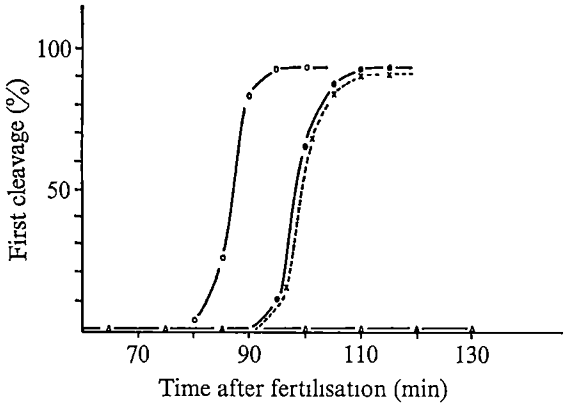


Fig. 6 Capacity of ammonia to substitute for sodium in initiating development. A 1% suspension of eggs was fertilised in seawater and, at 1 min after fertilisation, washed twice in choline-substituted seawater. Aliquots (5 ml) of these choline-arrested eggs were then immediately transferred to 50 ml of seawater (○), sodium-free choline substituted seawater (△), choline-substituted seawater containing 50 mM sodium (●), or choline-substituted seawater containing 5 mM NH_4Cl (×). The embryos were incubated at 17 °C and, beginning at 65 min, 2-ml samples were taken every 5 min and fixed in 5% formalin. The percentage of fully cleaved cells was then determined at each time point.

activation can be prevented by lowering the extracellular *p*H below 6.5, which prevents acid efflux. As with the amiloride effect, this is seen only during the first few minutes after insemination; embryos develop at least through first cleavage if placed at *p*H 6.0 after the first 10 min of development.

The fourth and most important observation stems from our finding that ammonia will initiate H^+ efflux in the absence of external sodium (Fig. 2). We found that these concentrations of ammonia can initiate the development of choline-arrested eggs, again in the absence of sodium. The capacity of ammonia to substitute for sodium is shown in the following experiment. Eggs were fertilised and transferred at 1 min to choline-substituted seawater containing either 50 mM sodium or 5 mM ammonia. Control eggs in regular seawater cleave at about 85 min (Fig. 6), whereas eggs transferred to Na^+-free seawater at 1 min do not cleave (pronuclei do not swell or fuse and no cytasters form). If eggs are transferred to choline seawater with either sodium or ammonia present, however, cleavage occurs—albeit slightly later than the control eggs (the 10-min delay probably results from the presence of choline).

The developmental behaviour of inseminated eggs is identical when either ammonia or Na^+ is present, demonstrating that the important factor in initiating development is not the presence of sodium *per se*. That it is the cytoplasmic *p*H change that is critical is suggested by the aforementioned induction of H^+ efflux by ammonia and also by the other amines which activate metabolism (1 mM nicotine and 5–10 mM procaine). This H^+ efflux induced by amines is accompanied by a parallel increase in the *p*H of cell homogenates. These findings, together with the lack of inhibition of amine-induced H^+ efflux by amiloride, indicate that the amines bypass the normal mechanism of coupling H^+ efflux to Na^+ influx. Moreno and Diamond have noted that simple amines can interact with Na^+ channels in frog bladder[15]. In eggs, they may be inducing one component only (H^+ efflux) of the vectorial exchange or substituting directly for sodium. Certainly the amines are not increasing cell *p*H through their action as weak bases. The *p*H change seen in homogenates prepared from ammonia or procaine-activated eggs can be accounted for completely by the induced efflux of H^+ ions (determined by back-titration of homogenates).

The mechanism of initiating the Na^+–H^+ transport system that begins 60 s after fertilisation is unknown. Alteration of the egg surface by physical, chemical and enzymatic treatments[7,8] activates metabolism and we have previously implicated a surface glycoprotein in egg activation[8]. This protein is released from the egg surface between 45 s and 120 s after insemination. The close temporal correlation between release of this protein and the beginning of the Na^+-sensitive H^+ efflux is consistent with the possibility that this protein acts as an inhibitor of the exchange. If so, the observed suppression of metabolism of partially activated eggs by concentrated solutions of this protein[8] could result from its rebinding to the cell surface and preventing Na–H^+ exchange, with a resultant lowering of cell *p*H. Alternatively, the cell surface proteins may be an additional but separate factor controlling egg activation.

These data should be considered in light of the metabolic transitions that occur at fertilisation. The egg is in a state of metabolic inhibition and is rapidly transformed into a metabolically active cell with striking increases in diverse enzymatic and structural processes. Ca^{2+} is involved in the initial phase[2–4]. The second phase, which can be directly activated by amines and which includes increased biosynthesis, seems to result from a nonspecific pervasive change in the cytoplasmic environment. Our data suggest that this pervasive change may be the increase in cytoplasmic *p*H. Although this change can be initiated independently of the Ca^{2+} phase by the various amines, the amine activation is an incomplete regimen in that a functional mitotic apparatus does not form and cleavage does not occur. All observed changes, Ca^{2+}, *p*H, and perhaps loss of cell surface protein, seem to be prerequisites for complete development.

Do similar regulatory mechanisms occur in other eggs and other kinds of cells? Calcium regulation of cellular processes is widespread, and the calcium ionophores which activate eggs[17] can also activate various metabolic processes in somatic cells (see, for example, ref. 16). Proton efflux associated with cell activation has so far been described only in sea urchin and *Urechis* eggs[18]; in these eggs it is one of the earliest post-fertilisation changes. Extracellular *p*H can alter cell activity[19], but to our knowledge, intracellular *p*H has not been seriously considered as an on–off metabolic regulator of other kinds of cells. It is intriguing to speculate that the transition of cells from actively dividing to a resting or G_0 state or from the G_0 to the actively dividing state may be mediated through changes in intracellular *p*H.

Supported by grants from the NSF, the NIH and the NRC of Canada We thank Elizabeth Baker for technical assistance and E. W. Byrd, Jr, D. Fanestil, A. B. Hastings, J. Miller and G. Somero for critical discussion, and N. Cross, D. Fox, T. Humphreys, K. Nealson, M. Somero and N. K. Wessells for criticisms of this manuscript.

λ repressor regulates the switch between P_R and P_{rm} promoters

Alfred Walz, Vincenzo Pirrotta & Kurt Ineichen

Biozentrum der Universität Basel, Klingelbergstrasse 70, CH-4056 Basel, Switzerland

The DNA region containing the O_R operator, P_R and P_{rm} promoters and their transcription initiations is sequenced. By binding to O_R, repressor turns off P_R, turns on P_{rm} and at higher concentrations turns off P_{rm}, regulating its own synthesis. P_{rm} mRNA is unique in beginning immediately with the initiation of translation, without a preceding leader sequence.

THE right hand operator–promoter region of phage λ is a complex regulatory structure containing the sites of action of at least three proteins which interact with specific DNA sequences: the λ repressor, RNA polymerase and the *tof* or *cro* gene product. The operator itself is a multiple structure containing at least three repressor binding sites[1,2]. The strongest of these sites overlaps partially with the site to which RNA polymerase binds and from which it initiates rightward transcription of the *tof* gene[3]. Because of this overlap, repressor binding prevents polymerase binding and therefore blocks transcription.

An additional promoter is located in the vicinity of O_R. This is the P_{rm} promoter, active in the transcription of *c*I, the repressor gene, in the lysogenic state. *In vivo*, the activity of this promoter is dependent on the earlier presence of repressor bound to O_R[4]. We have previously presented[3] arguments for the location of P_{rm} within the O_R sequence and predicted that, at high concentrations, repressor should block P_{rm} and therefore turn off its own synthesis, thus acting both as a positive and as a negative autoregulator.

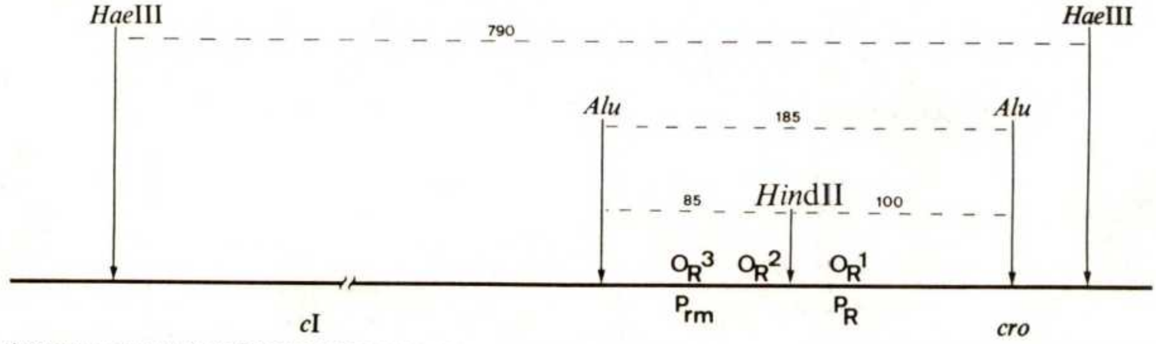
More recently, a mutation in P_{rm} has been localised in the O_R sequence[5,6] and the autoregulation of repressor synthesis has been demonstrated *in vitro* using as template DNA fragments produced by restriction enzymes.

In this article we report the sequence of the DNA region bounded by the *Hin*dII cut in O_R and the *Alu*I cut 85 base pairs to the left of it (Fig. 1). This region contains the repressor binding sites O_R2 and O_R3 and the beginning of the *c*I gene. We have used this DNA fragment for direct DNA sequencing using the method of Gilbert *et al.*[7]. In the presence of limited amounts of repressor this fragment or the *Hae*III 790 fragment from the same region are also good templates for P_{rm} transcription. We have sequenced the beginning of the mRNA species stimulated by repressor and we have located it in the DNA sequence. We find that, as predicted by our model, P_{rm} transcription initiates a few nucleotides to the left of O_R3. The message begins with AUG and is followed immediately by the codons specifying the amino acid sequence of the amino terminal of the λ repressor protein[8].

Sequence of the O_R-P_{rm}-*c*I DNA

The restriction endonuclease *Alu*I produces a DNA fragment from the O_R region of λ DNA, which is about 185 base pairs long and contains in the middle the *Hin*dII cleavage site which separates the operator primary site O_R1 from the rest of the operator. The *Alu* 185 fragment can therefore be terminally labelled with polynucleotide kinase, cleaved with *Hin*dII and the desired fragment, now labelled only at one 5′ end, separated by gel electrophoresis. The shorter fragment, 85 base pairs long, contains the secondary repressor binding sites O_R2 and O_R3 and must contain also the beginning of the *c*I gene. We have subjected this fragment, now labelled only at the *Alu* 5′ terminal, to the chemical sequencing method of Gilbert *et al.*[7]. Partial methylation with dimethyl sulphate renders the A and G residues sensitive to depurination and chain scission by β elimination. The products are analysed by gel electrophoresis. Strong bands correspond to cleavage at G residues and the weak bands to cleavage at A residues, since the former are methylated six times more rapidly than the latter. Hydrazinolysis in aqueous medium, followed by piperidine-catalysed β elimination, leads to cleavage at C and T residues. An increased specificity of cleavage is obtained by performing the hydrazinolysis in the presence of high ionic strength which leads to preferential reaction at C residues. The sequence is obtained by identifying successive bands present in the purine specific reactions or in

Fig. 1 Restriction endonuclease cleavage sites in the vicinity of O_R. Distances are shown in base pairs. The approximate location of the three repressor binding sites O_R1, O_R2 and O_R3 and of the two promoters P_R and P_{rm} are indicated. The dotted lines represent transcription of the *c*I gene and of the *cro* or *tof* gene.



the pyrimidine specific reactions. Figure 2 shows that the 3′ terminal sequence, though difficult to decipher, corresponds to the previously known sequence of the O_R2 and O_R3 repressor binding sites. The sequence towards the 5′ end according to the model should contain the P_{rm} promoter sequence and the initial part of the *c*I gene.

Repressor stimulated transcription

To identify the initiation of the P_{rm} mRNA in the sequence obtained above, we used the *Hae*III 790 or the *Alu* 185 restriction fragments as templates for transcription. In the absence of repressor we expect P_R transcription to be dominant. In the *Hae* 790 fragment this should yield a transcription product about 100 bases long. In the *Alu* 185 this product should be about 65 bases long. The P_{rm} transcript from *Hae* 790 should be much longer than the P_R transcript, while if the *Alu* 185 is used as template we expect the P_{rm} transcript to be a maximum of 45 bases long. Furthermore, increasing amounts of repressor in the transcription reaction should block P_R transcription, but stimulate P_{rm} transcription. Figure 3 shows that these expectations are borne out. Using the *Alu* 185 as template, a strong band about 65 bases long is produced in the absence of repressor and disappears at low repressor concentrations. This must be the P_R product. One band, about 35 bases long, is missing in the absence of repressor, appears at low repressor doses and disappears at higher doses. This must be the P_{rm} product. As observed in other systems, glycerol facilitates transcription[9]. We find that at low glycerol concentrations, transcription from P_{rm} is much less efficient even in the presence of suitable amounts of repressor.

Fig. 2 DNA sequence of the *Alu-Hin*dII fragment. Purified *Alu* 185 fragments were treated with 2 μg bacterial alkaline phosphatase for 1 h at 37 °C. After 4 phenol extractions, followed by 4 ether extractions, 1 nmol γ-^{32}P-ATP (400–800 mCi μmol^{-1}) and 5–10 units of polynucleotide kinase were added and the reaction mixture was incubated at 37 °C for 1 h. The labelled fragments were cleaved with *Hin*dII and the products, now labelled at only one 5′ end, were purified by gel electrophoresis on 0.7% Agarose–3% acrylamide gels in 0.09 Tris-borate (*p*H 8.2). The desired band was extracted from the gel and treated with dimethylsulphate (purine specific cleavage) or with hydrazine either low salt (T specific cleavage) or in 1 M KCl (C specific cleavage), according to the method of Gilbert *et al.*[7] and of Gilbert and Maxam (personal communication). Preferential cleavage at *A* is obtained by depurinating the methylated DNA at acid rather than alkaline *p*H. The products were analysed on a 40 cm gel containing 20% acrylamide, 7 M urea and 0.05 M Tris-borate (*p*H 8.2). Electrophoresis proceeded at 600 V for about 14 h. One glass plate was removed, the gel was wrapped in plastic film and autoradiographed at −20 °C (left). To obtain better resolution in the upper part of the gel, the glass plate could be replaced and electrophoresis could be continued with little loss in the definition of the bands (to the right, shown at slightly greater magnification). BPB and XC indicate the positions of the marker dyes which comigrate with fragments 10 and 29 bases long, respectively.

Sequence of the P_{rm} mRNA

To verify that the transcription product stimulated by repressor originates from the P_{rm} region and from the correct strand, we eluted the material from the gel and determined its sequence. Figure 4 shows an RNase T_1 fingerprint obtained by electrophoresis on cellulose acetate (*p*H 3.5), followed by chromatography on a PEI thin layer Analysis of the spots with pancreatic RNase permitted us to determine their sequence. The 5′ triphosphate end, which is barely visible at the lower left corner of the fingerprint, is pppAUG. A rapid inspection of the T1 oligonucleotide sequences shows that they are in fact complementary to part of the DNA sequence obtained from the *Alu* fragment. The distinctive $CACA_nG$ sequence corresponds to the CT_6GTG in the DNA sequence. The initial pppAUG corresponds to the CAT as shown in Fig. 5. No other ATG occurs in the $\mathscr{L}$ strand in this vicinity. We conclude that the repressor stimulated transcription originates from a unique site, copies the left strand and initiates with AUG.

Initiation of translation

The amino acid sequence near the NH_2 terminal of the λ repressor protein has been determined recently[8].

The initial 11 amino acids of this sequence fit perfectly with the DNA sequence that we have established and with the sequence of the P_{rm} mRNA. Unlike other known prokaryotic mRNAs, the P_{rm} message initiates immediately with a f-Met codon which is followed by the amino acid sequence of the protein. If the P_{rm} mRNA *in vivo* initiates at the same site as *in vitro*, it contains no leader sequence and thus no provision for a sequence complementary to 16S ribosomal RNA[10,11]

Structure of the O_R operator

The sequence upstream of O_R3 shows first of all that there is nothing recognisable as a fourth repressor binding site. The characteristic sequence TATCACCG which constitutes the most strongly conserved feature of the repressor recognition sites[1,12] is missing or is drastically altered. The fourth repressor tetramer which was observed to bind at very high repressor concentrations[13], was probably due to a relatively nonspecific interaction stabilised by protein interaction with the preceding repressor tetramer. There are then only three functional repressor binding sites in O_R. Recent experiments indicate that this is also the case for O_L (V. P., unpublished). In O_R, the primary site and O_R2 contain sequence elements necessary for the recognition of the P_R promoter by RNA polymerase. Occupation of these sites by the repressor therefore leads to repression of P_R transcription. In consequence these two sites are the targets of mutations which result in constitutive expression of the *tof* gene[1]. Smith *et al.*[5], using deletions which enter O_R from the left, find that

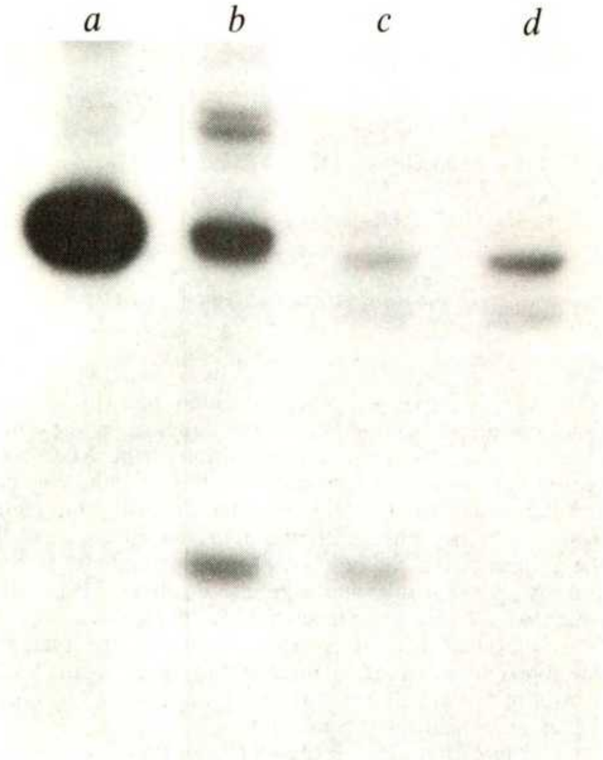

Fig. 3 Turn-on and turn-off of P_{rm} transcription. 1 pmol of *Alu* 185 fragment was incubated at 20 °C for 10 min with (*a*) no repressor, (*b*) 0.5 µl, (*c*) 2 µl and (*d*) 10 µl of λ repressor in 50 µl containing 20 mM Tris (*p*H 7.9), 0.1 mM EDTA, 0.1 mM dithiothreitol, 8 mM $MgCl_2$, 40 mM KCl and 15% glycerol. RNA polymerase (2 µg or 1.7 U) and ATP (200 µM final concentration) were added and incubation was continued for 10 min at 37 °C. 1 µl of 2 mg ml^{-1} heparin was then added, followed 2 min later by GTP and UTP at a final concentration 10 µM and α-^{32}P CTP (100 mCi μmol^{-1}) at 2 µM. The reaction was stopped after 10 min at 37 °C by a phenol extraction and ethanol precipitation. The material was analysed on a 12% acrylamide gel containing 7 M urea and 90 mM Tris-borate (*p*H 8.2). The strong band in (*a*) is the P_R transcript while the band that appears in (*b*) and (*c*) is presumed to be the P_{rm} transcript. The weak band, of roughly the same size as the P_R transcript, which seems to be stimulated by repressor, was also sequenced and found to be due to contaminating traces of a different *Alu* fragment.

the first two sites, but not O_R3, are required for effective repression.

P_{rm} promoter

In an earlier article[3] we have pointed out a remarkable degree of symmetry centred around the middle of O_R2. This symmetry is absent in O_L because of the different disposition of the repressor binding sites. As a consequence of this symmetry, O_R contains another sequence similar to that of P_R but with orientation opposite to it. This, we proposed, was the P_{rm} promoter. This conclusion was supported by the finding that a mutation in P_{rm} is located between O_R2 and O_R3 (refs 5, 6).

The symmetry results in substantial sequence homology between the P_R and the P_{rm} region, but it is not perfect. If the P_R and P_{rm} sequences are aligned as in Fig. 6, good agreement is obtained only if half of the sequence is displaced by one base. Therefore, assuming that the P_R sequence is representative of a good promoter, some adjustment needs to be made in order for P_{rm} to resemble it. This probably accounts for the finding that in the absence of repressor, P_{rm} is inactive. By binding to O_R1, the repressor in some way facilitates the recognition of P_{rm} by the RNA polymerase. We do not yet know the mechanism of this facilitation.

A possible interpretation is suggested by the observation that RNA polymerase is unable to bind to the *Hin*dII fragment containing O_R1 (ref. 14) even though the site at which it forms the initiation complex is entirely to the right of the *Hin*dII cleavage site (Fig. 7). We conclude that the polymerase must interact with the region of O_R2 in order to bind to the P_R promoter. The symmetric arrangement of P_R and P_{rm} suggests that the same region is required for binding to P_{rm}. This region would then be a non-directional recognition site from which RNA polymerase could move in either direction to form the initiation complex at P_R or P_{rm}. Repressor might activate P_{rm} simply by blocking the stronger promoter P_R and removing a competitive binding site for polymerase. Alternatively the repressor might change the conformation of the DNA in the vicinity of O_R2–O_R3, making it possible for the polymerase to recognise P_{rm}.

We do not know yet what particular sequence features at what positions are required for RNA polymerase binding. The substantial variety in the promoter sequences determined so far, suggests that the polymerase can accommodate a wide range of sequences. The fact that single base changes can inactivate promoter sites indicates, however, that in a given sequence, certain nucleotides play a key role. For example, the *sex* 1 mutation in P_L affects a

Fig. 4 RNase T_1 fingerprint of P_{rm} transcription initiation. In this case the template used was the *Hae* 790 fragment. In the transcription reaction the ATP concentration was 200 µM. The other 3 nucleotide triphosphates were labelled and at 1.7 µM. A partial transcription product about 45 bases long was eluted from the gel as described previously[2], digested with RNase T1 and fractionated in the first dimension by electrophoresis on cellulose acetate (*p*H 3.5). This was followed by chromatography in the second dimension on a PEI cellulose thin layer with 2 M pyridine formate (*p*H 3.5) and 7 M urea. The spots were analysed by digestion with pancreatic RNase and electrophoresis on DEAE cellulose paper (*p*H 3.5).

GC pair in the position shown in Fig. 6[1]. The corresponding position in $\mathrm{P_{rm}}$ is also of crucial importance. This is the site where Meyer *et al.*[6] place the $\mathrm{P_{rm}}$ 116 mutation and it is also the site where the $\mathrm{P_{rm}}$ sequence goes out of register with that of $\mathrm{P_R}$. Significantly, the effects of the *sex* 1 mutation can be compensated by the presence of glycerol in an *in vitro* transcription reaction[9]. This suggests that both in the *sex* 1 mutation and in the normal $\mathrm{P_{rm}}$, the limiting step is the opening of the strands by the polymerase to form the so-called "open" complex (for review see refs 15 and 16).

Another possible recognition element is the heptanucleotide which can be discerned, with certain variations, in all RNA polymerase binding sites, 6–7 nucleotides upstream of the transcription initiation site[17]. This heptanucleotide, whose canonical form is TATpupuTpu, is present in $\mathrm{P_R}$ as GATAATG. In $\mathrm{P_{rm}}$ it is further changed to GATAGAT.

Fig. 6 Comparison of promoter sequences. The λ $\mathrm{P_L}$, $\mathrm{P_R}$ and $\mathrm{P_{rm}}$ sequences are aligned to emphasise their homology. The arrows indicate the initiation of transcription. Maximum homology is obtained if part of the $\mathrm{P_{rm}}$ sequence is displaced by one base. The sites of the *sex* 1 and of the $\mathrm{P_{rm}}$ 116 promoter mutations[6] are indicated. The dotted line encloses the heptanucleotide generally found in RNA polymerase binding sites[17].

$\mathrm{P_{rm}}$ mRNA has no leader sequence

All prokaryotic mRNAs so far studied contain a stretch of variable length preceding the initiator AUG codon. This stretch has been called the leader and is thought to be important in directing the binding of ribosomes to the translation initiation site[10]. In contrast, the $\mathrm{P_{rm}}$ mRNA begins immediately with the initiator codon and lacks the polypurine tract which is thought to interact with the 3′ end of the 16S ribosomal RNA. If the $\mathrm{P_{rm}}$ mRNA begins at the same site *in vivo*, we must conclude that in this case, ribosome interaction with the initiation site on the mRNA is entirely dependent on the recognition of the AUG codon. We do not know the significance of this finding. We speculate, however, that the lack of other stabilising interactions would make the binding of ribosomes less efficient and limit the utilisation of the mRNA. Moreover, attack at the 5′ end by *exo*V would immediately inactivate $\mathrm{P_{rm}}$ mRNA which would then be expected to have an unusually short functional half life. It is remarkable that the phage has developed such elaborate mechanisms both at the level of transcription and of translation to limit the expression of the *c*I gene in the lysogenic state.

Upon infection of a sensitive cell, on the other hand, the *c*I gene is transcribed from a different promoter, the so-called $\mathrm{P_{re}}$ promoter, located to the right of the *tof* gene[4]. Transcription originating from this promoter has potentially a leader region several hundred nucleotides long which contains the anti-sense sequence of the *tof* gene and includes the $\mathrm{O_R}$ sequence. This region, as far as we know, is not translated. In this case, the sequence preceding the initiator codon AUG contains all the features of a typical ribosomal binding site. There is in fact a GGTGAT in the operator sequence which is complementary to the AUCACC close to the 3′ end of the ribosomal 16S RNA. The sequence contains a UUU which is also found in several other ribosomal binding sites [11,18] and, finally, three terminator codons in

Fig. 7 The $\mathrm{P_{rm}}$-$\mathrm{O_R}$-$\mathrm{P_R}$ region. The two promoters are shown symmetrically disposed and overlapping the two ends of the operator. In $\mathrm{P_R}$, RNA polymerase forms the tight binding and initiation complex at the site indicated, partially overlapping $\mathrm{O_R1}$. A presumed corresponding site for $\mathrm{P_{rm}}$ is shown by a dashed line. The initiation of transcription is indicated by arrows. The entire structure is symmetrically arranged around the centre of $\mathrm{O_R2}$. This is the region where the RNA polymerase might form the initial recognition complex. Repressor bound to $\mathrm{O_R1}$ would then steer the polymerase to the $\mathrm{P_{rm}}$ binding and initiation site.

phase precede the initiator AUG codon.

To conclude, we note that *tof* mRNA, like the $\mathrm{P_{rm}}$ mRNA, also begins with an AUG This similarity may not be entirely fortuitous. It is in keeping with the above-mentioned symmetry of the entire $\mathrm{O_R}$ region and with the fact that *tof* product, like the *c*I product, acts as a repressor, albeit a weak one. Its sites of action, like those of the *c*I repressor, are $\mathrm{O_L}$ where it performs the eponymous function of turning off the *N* operon, and $\mathrm{O_R}$, where it turns off transcription of $\mathrm{P_{rm}}$ and of $\mathrm{P_R}$ and hence its own transcription[19]. In short, the *tof* product may formally be considered a mini version of the *c*I repressor. In the *tof* mRNA, however, the initial AUG is not the start of translation because it is followed two triplets later by a UAA codon in phase.

We thank T Bickle and P. Schedl for discussions and criticism. This work was supported in part by a grant from the Swiss National Foundation for Scientific Research.

letters to nature

The second highly polarised radio outburst in Cygnus X-3

We detected a second outburst with a high degree of linear polarisation from Cyg X-3 in August 1975, following the alert by Kawajiri[1] The first such outburst was observed in May 1974 (refs 2 and 3) Here we report observations of both polarised outbursts as well as of an unpolarised outburst in January 1975. At 8 GHz the observed polarisation position angle was the same for both polarised outbursts. The Faraday rotation measure associated with the source is much larger than previously reported[2] We suggest that the orientation of the magnetic field in the source and the rotation measure are both stable with time In addition, we find that the highly polarised outbursts decay significantly more slowly than the unpolarised outbursts

All measurements were made with the University of Michigan 85-foot paraboloid operating at frequencies of 8 and 14.5 GHz. The equipment and on-off observing techniques used at 8 GHz have been described previously[4–6]. Similar equipment and techniques were used at 14.5 GHz. All the observations were made with linear polarimeters except for those made at 8 GHz on May 26 and June 2, 1974 and on August 27–28, 1975, which were obtained with a single-horn circular polarimeter. Observations of Cyg X-3 were alternated with observations of the standard sources Cyg A or DR21 to determine the flux density calibration. Daily averages of the data for the polarised outbursts are presented in Table 1 The total flux density measurements have been corrected for confusion effects by the addition of 0.071 Jy at 14.5 GHz and the subtraction of either 0.73 or 0.49 Jy at 8 GHz for observations made with the linear or circular polarimeters respectively. The standard errors include the statistical noise and the uncertainties in the antenna gain and telescope pointing

The total and polarised flux densities for August and September 1975 are displayed in Fig 1. Only the decay phase of the outburst was observed Observations[7] at 5 GHz indicate that the maximum flux density occurred on August 22 or 23, 2 or 3 d before our measurements began From August 26 to September 3, the decay of the total flux density at 8 GHz was exponential with time. The line through the 8-GHz data points is a least squares fit to the data from August 26–27 to September 1–2 and represents an e-folding time of 86±1 h The 14.5-GHz data are consistent with the same exponential decay rate The spectral index from 14.5 to 8 GHz during the exponential decay remained at $\alpha = -0.65 \pm 0.06$ where $\alpha = (\Delta \log S_\nu / \Delta \log \nu)$. The same spectral index appears to fit the data at 5 GHz (ref. 7) which indicates that the source was transparent above 5 GHz from August 24 to September 5. After September 3 the rapid exponential decay ceased and the total flux density slowly and irregularly declined until September 20. By September 10 the flux density seems to have been nearly the same from 5 GHz to 14.5 GHz, coresponding to a spectral index $\alpha \sim 0$.

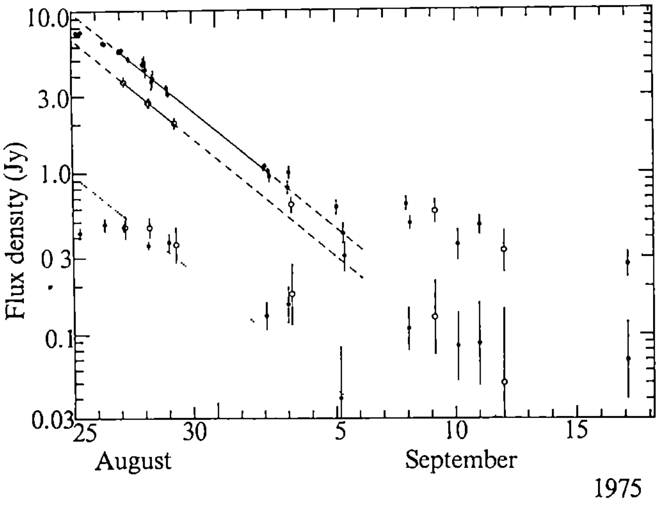

Fig. 1 Semilog plot of total and polarised flux density against universal time at 8.0 (●) and 14.5 (○) GHz for Cyg X-3. The total flux density measurements in the upper portion of the plot are 40-min averages of the data. The polarised flux density measurements in the lower portion are daily averages. The two lines through the total flux density measurements are fits to an exponential decay with time for the data where the lines are solid. The dotted line through the polarised flux density measurements represents a constant 10% degree of linear polarisation for the exponential decay of the total flux density at 8 GHz.

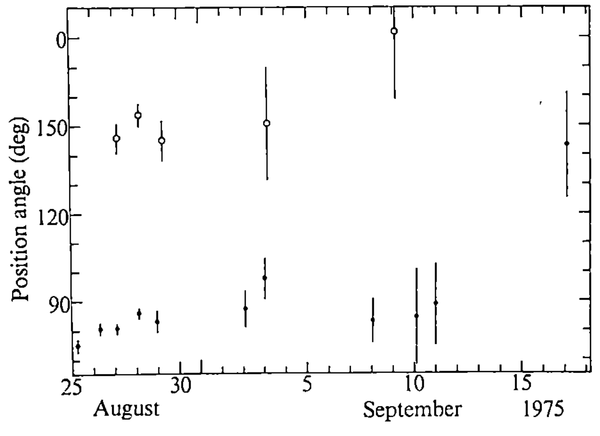
It has been noted that the decay of the first September 1972 outburst evolved from an exponential to a power-law time dependence with the exponential phase lasting longer at higher frequencies[8]. The same phenomenon may have occurred during this outburst. The irregular flux variations and the apparent change in the spectral index indicate, however, that renewed injection or acceleration of particles may have obscured the decay of the outburst after September 3. Hence, fits to the data extending after September 3, such as the one made at 5 GHz (ref. 7) may not give a true indication of the decay process.

No circular polarisation was detected in either polarised outburst. A 2σ upper limit of 0.5% for the degree of circular polarisation was obtained on August 27–28, 1975. Our measured degree of circular polarisation of 0.4±0.4% for the May 1974 outburst agrees with the upper limit of 0.5% obtained by Seaquist *et al.*[2].

During the August 1975 outburst the degree of linear polarisation increased to > 10% at both frequencies, as illustrated in Fig. 1. The level of polarisation at 8 GHz is comparable to that observed by us and by Seaquist *et al.*[2] during the May 1974 outburst. Although the total flux density was already decreasing when we started observing on August 25, 1975, the polarised flux density did not begin to decrease until August 27. The increase in the degree of polarisation with time, and the fact that the degree of polarisation was significantly higher at the higher frequency (14.5 GHz) are both similar to the pattern observed during the May 1974 outburst[2,3].

Fig. 2 Linear polarisation position angle against universal time at 8.0 (●) and 14.5 (○) GHz. The points represent daily averages of the data.



The position angles of the linear polarisation for the August 1975 outburst are shown in Fig. 2. The average position angle observed at 8 GHz from August 25 to September 3 of 81.1±1.0° is the same within uncertainties as the value of 80.5±2.2° observed by us for the May 1974 outburst The position angle may have changed at 8 GHz by ~ 10° during the 1975 outburst. The average position angle observed at 14.5 GHz was 150±3°. If the difference in position angle is caused by Faraday rotation, the rotation measure must be at least −1,265±56 rad m^{-2}. This value is more than twelve times that derived from data at the frequencies 2.7 and 8.1 GHz (ref. 2). Observations at 4.2 GHz for the May 1974 outburst[3] also indicate that the original determination of the rotation measure was too small because of the $n\pi$ ambiguity in the amount of rotation at 2.7 GHz. The excellent agreement of the observed position angles for the two polarised outbursts strongly suggests that the rotation measure and intrinsic position angle were the same for both outbursts. If the position angles of the two outbursts were completely independent, the probability that the difference would be not more than 0.6° is 0.7%. The probability that the difference would be not more than the quadratically summed error of 2.4° is 2.7%. We have fitted the observed position angles from both outbursts together and find that a rotation measure of −1,233±10 rad m^{-2} is consistent with all the data. The intrinsic position angle of the linear polarisation was 0±3°.

The stability of the 8-GHz polarisation position angle during the outbursts and between the first outburst and the second indicates that most of the Faraday rotation must occur in a region which is unaffected by the evolution of the outbursts. It is extremely unlikely that the rotation measure within the expanding emitting region would be the same for two separate bursts or that the internal rotation measure would not change as the emitting region expanded. The region producing the observed Faraday rotation could be either the long path through the Galaxy between Cyg X-3 and the Earth or a volume around Cyg X-3 in which material has accumulated from previous activity in the source. The sign of the rotation measure is the same as that observed for other sources in the Cygnus direction through the Galaxy, although the magnitude is much larger[9,10]. If the distance to Cyg X-3 is taken as 11 kpc (refs 11 and 12), the observed rotation measure could be produced by an average longitudinal component of the magnetic field of 10^{-6} gauss and an average electron density of 0.14 cm^{-3}. These are reasonable values, especially since the source is located on the far side of the Cyg X complex of H II regions.

The similar degrees of polarisation and the agreement between the polarisation position angles for the two outbursts suggest that the structure of the magnetic field in Cyg X-3 was the same for both outbursts The periodicity observed in the radio[6,8], infrared[13] and X-ray[14] emissions indicates that Cyg X-3 is a rotating or revolving system with a period of 4.8 h. The absence of large changes in the polarisation position angle data indicates that the magnetic field in the emitting region is oriented near a direction parallel or perpendicular to the angular momentum axis of the object.

Since the intrinsic position angle of the linear polarisation produced in an optically thin source is perpendicular to the transverse projection of the magnetic field, the axis of

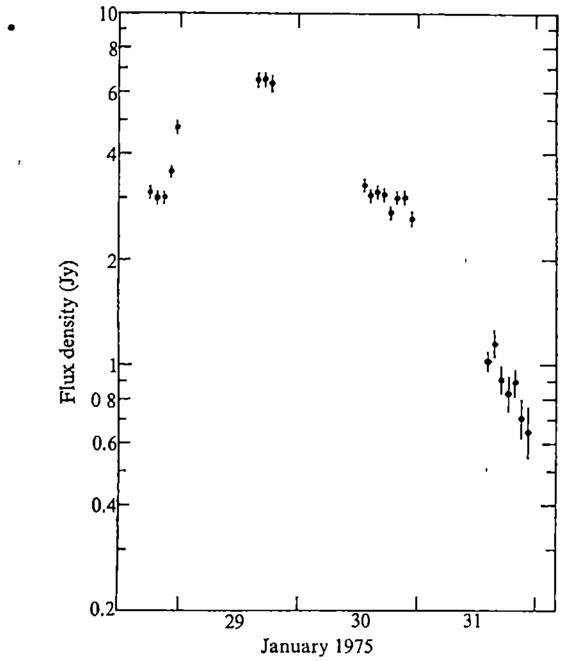


Fig. 3 Semilog plot of total flux density against UT at 8.0 GHz for Cyg X-3. The points represent 40-min averages of the data.

rotation or revolution of the system should be near a position angle of 0° or 90°. Any model for the radio emission from this source, especially those involving expansion where the particles control the magnetic field[15,16], must explain the observed stability of the field structure.

Observations at 8 GHz of an unpolarised outburst in Cyg X-3 during January 1975 are shown in Fig. 3. The average degree of linear polarisation from our 23 measurements was 1.3±0.5% at a position angle of 66±12°. The characteristic time for the decay of the total flux density was ~27 h which is similar to the decay times found for the other unpolarised outbursts[5,17]. It is noteworthy that the two highly linearly polarised outbursts have decayed significantly more slowly than all the other observed outbursts, of which four are known to have been unpolarised[2,6,18,19].

If there is a correlation between the decay rate and the existence of linear polarisation, it is an important feature which must be explained by any model for the radio outbursts in Cyg X-3. For instance, there is a natural correlation between the decay rate and the amount of linear polarisation if the absence of polarisation in the unpolarised events is caused by Faraday depolarisation and the energy losses of the radiating particles arise from thermal bremsstrahlung. This energy loss mechanism has been suggested to explain the exponential nature of the decay[5]. The difference in the amount of thermal matter required for polarised and unpolarised outbursts is much larger, however, than the difference required to explain the different decay rates. On the other hand, it is not obvious why a correlation between the decay rate and the state of polarisation would exist for expanding source models in which the energy losses are due to adiabatic expansion[15] or to both adiabatic expansion and synchroton radiation[16] Source models for Cyg X-3 must account for the smaller degree of polarisation at lower frequencies during the polarised outbursts. For example, the ratio of the degree of polarisation at 8 GHz to that at 14.5 GHz was 0.54±0.06. It has been suggested that this depolarisation effect arises from Faraday depolarisation[2]. This explanation is, however, hard to reconcile with the stability of the polarisation position angle observed at 8 GHz.

We thank F. T. Haddock, T. V Seling, G E. Latimer and K. G. Holmes for making these observations possible. This research was supported by grants from the NSF.

Competition of neutrino and gravitational radiation in neutron star formation

We look here into the possibility that neutrino radiation (rather than gravitational radiation) may be the dominant way by which non-radial pulsations are damped out in a collapsing star. If true, such a result implies that estimates and hopes to detect gravity waves from supernovae explosions may have been overly optimistic.

It has been known for some time that neutron stars and black holes are probably the collapsed central remnants of a supernova explosion. These objects presumably originate from the collapse of the cores of sufficiently massive ($M \gtrsim 7M_\odot$) stars[1], following the cessation of thermonuclear burning. Although at the present no completely consistent detailed theory exists showing exactly how the collapse of the core and the subsequent supernova explosion take place, there does exist a general model[2] for the final stages of stellar evolution and supernovae explosions. According to this, the electrons of a sufficiently massive stellar core, due to the high density and temperature, get absorbed by the protons, through $p+e^- \rightarrow n+v$. At the same time, huge numbers of neutrinos, resulting from this and other thermal processes (pair annihilation, plasma decay, bremsstrahlung) (refs 3 and 4) are emitted, taking away most of the gravitational energy of the collapse. These neutrinos possibly drive the ejection of the overlying stellar mantle, while the neutron-rich core further collapses to a condensed remnant.

The leftover remnant is of very high density (10^{14}–10^{15} g cm^{-3}) and its radius will eventually be only a few times its Schwarzschild radius. This implies that general relativistic effects may be important in situations involving neutron stars. In particular, the possibility of gravitational radiation emission from non-radially pulsating neutron stars has been extensively examined and it has been shown that gravitational waves can carry away the pulsational energy, thus damping out the star's oscillations. (Such non-radial pulsations presumably might occur during the collapse and formation of the neutron star.) Some workers have estimated[5] that the energy emitted in gravitational radiation in such an event would be sufficient to trigger existing or future gravitational radiation detectors. Consequently one might expect detectable gravitational wave pulses to be associated with supernovae explosions from the non-radial pulsations of the newly formed neutron stars.

As previously discussed, however, the dominant mechanism by which energy is carried away from the collapsing core is by neutrinos rather than gravitational radiation, the latter coming into play only at the very late stages of the collapse. This implies that neutrino radiation might also contribute to the decay of the non-radial oscillations of the collapsing core and the newly formed neutron star, possibly damping out these oscillations much faster than gravitational radiation.

To give a more quantitative answer to this question, the effects of neutrino radiation on the non-radial oscillations of such objects have been examined (D. Kazanas and D. N. Schramm, unpublished). The oscillations are assumed small enough so that the linear approximation in the perturbation is sufficient. The equilibrium configuration is assumed to be static (the velocity of the fluid $\bar{u} = 0$ when in equilibrium) and homogeneous ($\nabla\rho_0 = 0$). (The subscript zero denotes unperturbed quantities.) Its mass was taken to be $0.75M_\odot$ (to avoid an overestimate of the central temperatures) and it was assumed to obey an ideal gas law (not unreasonable for such a hot neutron gas). Together with the density, these completely specify the equilibrium configuration (the radius, and temperature and pressure distributions). Table 1 gives the radii and central temperatures for such a configuration for four different density regimes. (Of course, the figures for the highest density are only formal, because the equation of state then differs significantly from that of an ideal gas.) Assuming also an $\exp(i\sigma t)$ time dependence for all perturbed quantities, one can estimate a damping time scale from the neutrino radiation. This will be, approximately, the total kinetic energy of the perturbation, E_{tot}, divided by the rate at which energy is lost by neutrino radiation, dE_ν/dt. This neutrino damping time scale is, as shown elsewhere (D. Kazanas and D. N. Schramm, unpublished), given by

Table 1 Variation of central temperature and radius with density for a neutron star

ρ(g cm^{-3})	T(10^9 K)	R(km)
10^{12}	84	70.7
10^{13}	181	32.8
10^{14}	389	15.2
10^{15}	839	7.0

$$\frac{1}{\tau} = \frac{dE_\nu/dt}{E_{tot}} = \frac{1}{2}\frac{(\Gamma-1)\int\delta L(\delta\rho/\rho_0)_a dV}{(\sigma_a{}^2/2)\int(\delta r)_a{}^2\rho_0 dV}$$

where the integrals extend over the volume of the configuration and where Γ is the adiabatic index, δL the perturbation of the neutrino luminosity in erg s^{-1} cm^{-3}, and the subscript a denotes that the quantities have to be evaluated for the corresponding adiabatic solution (with $L = 0$). The expression for the quantities $(\delta r)_a$ and $(\delta\rho/\rho_0)_a$ and values for σ_a can be found in the literature[6].

One can now evaluate the damping times with δL corresponding to a particular neutrino production mechanism. Using only the dominant thermal neutrino production process, which for the densities and temperatures involved, appears to be pair annihilation, one can obtain upper limit estimates of the damping times due to neutrino radiation. The results for the four different density regimes are shown in Table 2.

It is interesting to compare these to the corresponding damping times due to gravitational radiation. A variational calculation[7] gives $t = 10$ s for $\rho = 10^{14}$ g cm^{-3} and $t = 0.4$ s for $\rho = 10^{15}$ g cm^{-3}. For lower densities gravitational radiation is essentially absent and thus $\tau_G \gg \tau_\nu$.

Table 2 Density dependence of neutrino-damping time

ρ(g cm^{-3})	σ_a(s^{-1})	τ(s)
10^{12}	1,531	0.7
10^{13}	4,842	5×10^{-2}
10^{14}	15,310	10^{-3}
10^{15}	48,416	2×10^{-6}

The implication of the above result is easy to see. It seems that neutrino radiation, by more rapid damping of the non-radial oscillations of a newly formed neutron star in a supernova explosion, would hinder gravitational radiation, thus reducing the possibility of its detection.

We would like to acknowledge discussion with W. D. Arnett, K. Hainebach, J. Lattimer, M. Murphy and in particular with D. L. Tubbs on this problem. This work was supported in part by the NSF and NASA.

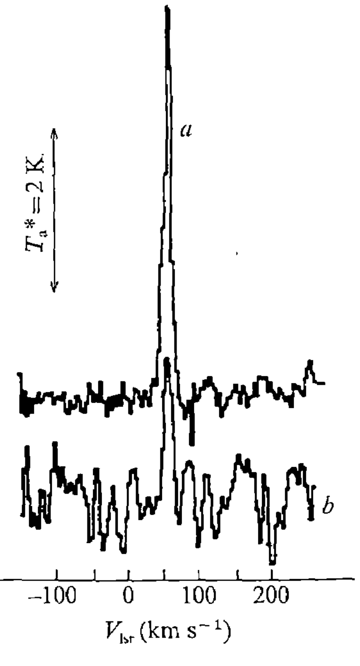
Detection of interstellar HN^{13}C

INTERSTELLAR hydrogen isocyanide (HNC) was first tentatively identified[1] on the basis of a calculated frequency for the $J=1\rightarrow0$ transition of the most abundant isotopic species H^{14}N^{12}C. The observed interstellar line was quite strong and widespread in the galaxy. A more definitive identification of the observed U90.7 emission line (90,663.6 MHz)[2] by searching for other isotopes was not possible because of the large uncertainties in the calculated molecular structure of HNC, and the corresponding large uncertainties in the calculated transition frequencies for H^{14}N^{13}C and H^{15}N^{12}C. Hydrogen isocyanide is very short lived in terrestrial laboratory conditions, and therefore it has proven difficult to measure the rotational spectrum directly. The $J=0\rightarrow1$ transition has, however, been recently measured independently by three groups[3-5] and the frequency of the major isotope is in excellent agreement with that of U90.7. The laboratory spectroscopy has also

Fig. 1 HN^{12}C (*a*) and HN^{13}C (×10) (*b*) in W51. Note the HN^{12}C line is broader: resolution = 1 MHz (≃3.3 km s^{-1}).



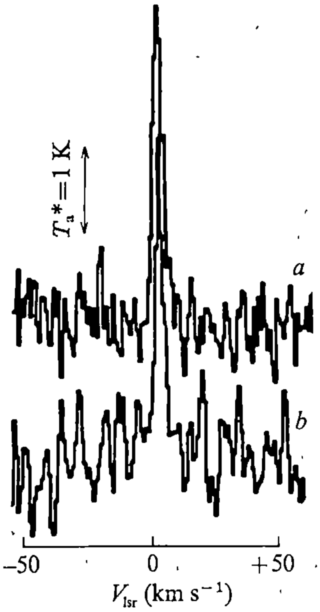


Fig. 2 HN^{12}C (*a*) and HN^{13}C (×10) (*b*) in DR21 (HCN peak). Note HN^{12}C line is significantly broader: resolution = 250 kHz (≃0.83 km s^{-1}).

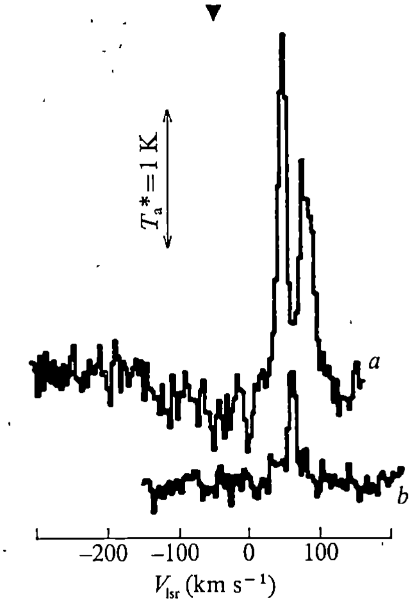
Fig. 3 HN^{12}C (*a*) and HN^{13}C (*b*) in Sag B2. Note gross difference in line profiles, both to same scale. Resolution = 1 MHz (≃3.3 km s^{-1}).



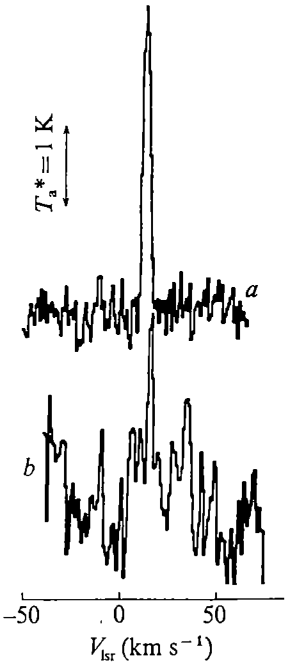


Fig. 4 HN^{12}C (*a*) and possibly HN^{13}C (×10) (*b*) in NGC2264. Resolution = 250 kHz (≃0.83 km s^{-1}).

yielded the ^{13}C isotope transition frequency[4]. Immediately following this measurement, we searched for and detected the HN^{13}C $J=1\rightarrow0$ rotational spectral line at 87,090.6 MHz in the galactic molecular source W51 (Fig. 1) on the NRAO 11-m telescope in March, 1976. Because of calibration problems with our receiver, we simultaneously observed the ^{12}C isotope so that relative abundance determinations might ultimately be made from our data. Appropriately, W51 was the source in which Snyder and Buhl first detected the $J=1\rightarrow0$ transition of HN^{12}C. In addition, the HN^{13}C line was detected in DR21, Sag B2, and possibly also NGC2264 and IRC+10°216 (Figs 2–5). All of these sources also showed the HN^{12}C emission line. In addition, we detected HN^{12}C in W3 (Fig. 6), but were unable to detect the ^{13}C isotope there due to equipment failure. These results are summarised in Table 1.

We attempted to refine the HN^{13}C rest frequency in the narrow line source DR21. Assuming that HN^{13}C occurs at the common velocity of −3 km s^{-1} for this source position, our observations indicate a rest frequency of 87,090.71 (0.25) MHz. This compares favourably with our laboratory data and those of Creswell *et al.*[5]. Snyder and Hollis's[6] rest frequency for HN^{12}C of 90,663.37 MHz indicates, however, a velocity of −5.25 km s^{-1}. This would necessitate a rest frequency of 87,091.36 MHz for HN^{13}C which is further from the laboratory data than one would like. Thus our data indicate the HN^{13}C frequency to be slightly higher in frequency than our laboratory measurement. This is also more consistent with our data in W51 and Sag B2 (taken with lower resolution).

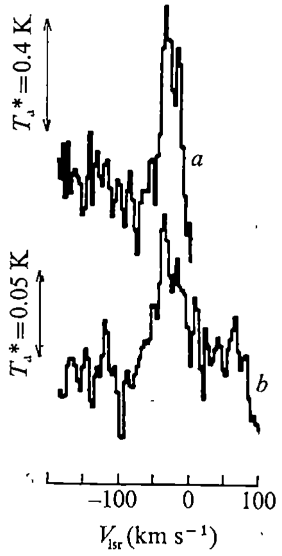
Table 1 Results of observations

Source name	RA (1950.0)	dec. (1950.0)	T_a* HN^{12}C (K)	T_a* HN^{13}C (K)
	(h min s)			
W51	19 21 23	+14° 24′ 30″	4.8	0.18
DR21	20 37 10	42° 09′ 00″	3.3	0.39
Sag B2	17 44 11	−28° 22′ 30″	2.8 (complex)	0.95
NGC2264	6 38 28	9° 32′ 06″	4.1	(0.27 ?)
IRC+10°216	9 45 15	13° 30′ 40″	0.6	(0.11 ?)

T_a* is antenna temperature divided by the beam efficiency corrected to outside the Earth's atmosphere.

Our Sag B2 spectra (Fig. 3) are very interesting. The HN^{12}C spectrum displays a double peaked structure with a profound dip in the middle. A similar double structure has also been observed in N_2H^+ (ref. 7) and the $J=2$–1 transition of ^{12}C^{32}S (ref. 8) (we observed the $J=2$–1 of ^{13}C^{32}S to be a single broad feature centred on roughly 60 km s^{-1}). HN^{13}C, however, displays a very narrow feature almost exactly centred on the HN^{12}C dip, with a weak broad base underneath. The most straightforward interpretation of these data is that the HN^{12}C is optically thick and self absorbed while the HN^{13}C is not. The position of the narrow HN^{13}C peak is consistent with this interpretation, as is the broad base. The very narrow HN^{13}C feature is,

Fig. 5 HN^{12}C (*a*) and possibly HN^{13}C (*b*) in IRC+10°216. Note scales are unrelated. Resolution = 1 MHz (≃3.3 km s^{-1}).



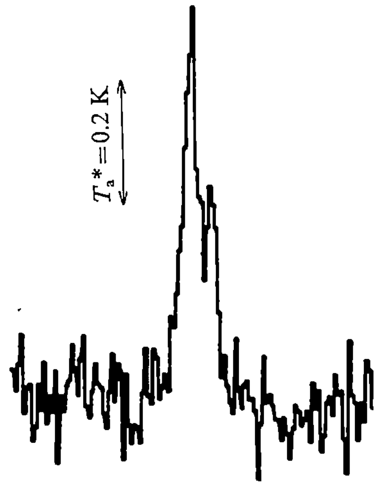


Fig. 6 HN^{12}C in W3. No data were obtained on HN^{13}C due to equipment problems. Resolution = 250 kHz ($\simeq$0.83 km s^{-1}).

however, intriguing and we cannot help but be impressed with the possibility that the HN^{12}C and HN^{13}C are not spatially coexistent. Perhaps both conditions occur to some extent. One interpretation of the extremely narrow HN^{13}C feature is that it results from a localised region considerably enhanced in ^{13}C. This problem is certainly worthy of further study. Similar effects in the isotopes of HCN have previously been observed by R. A. Linke (private communication) and are currently under study by him (and coworkers).

We thank the staff of the NRAO at Tucson, and especially Dewey Ross and Jack Cochran. We also thank the University of Kentucky Graduate School and the Australia Research Grants Committee for support. NRAO is operated by Associated Universities Inc. under contract with the NSF.

The second *Z*-propagation window

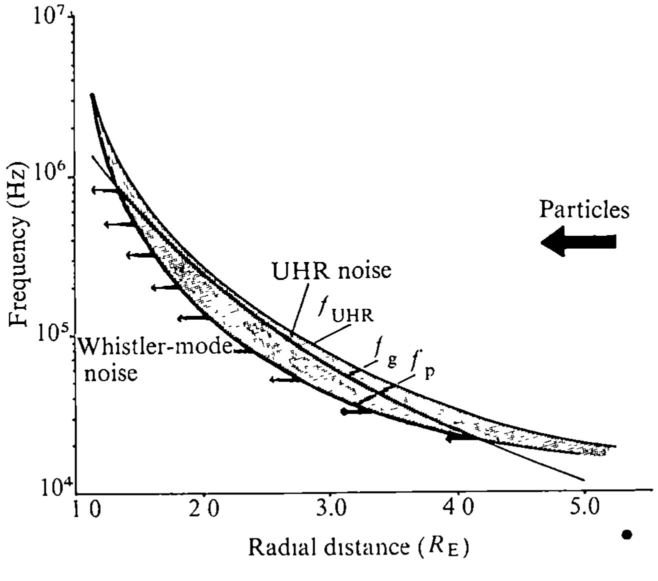
ELLIS[1,2] investigated the condition in the ionosphere under which an upgoing ordinary radio wave is converted, through a coupling process, into an upgoing extraordinary wave in the *Z* mode. (Propagation in the *Z* mode requires the presence of both an ionised gas and a magnetic field; hence such waves cannot be received in free space.) This occurs for a wave incident on the ionosphere from below with its wave normal close to a critical direction in the magnetic meridian plane. This direction is such that when the wave reaches the level where $X = 1$, which is normally a complete reflector for the ordinary wave, its wave-normal direction has become close to the magnetic field line direction. The symbols X and Y are as usually defined in magnetoionic theory (see Ratcliffe[3]). The level $X = 1$ becomes semi-transparent for a cone of angles centred on the critical direction. This cone is called the 'Ellis window'. The *Z*-mode waves are reflected at a higher level where $X = 1+Y$. Here I wish to draw attention to a window which is relevant to the escape of *Z*-mode radiation produced naturally in the topside ionosphere.

It is well known from satellite observations that radio noise is produced by charged particles streaming through the magnetosphere and ionosphere (see Mosier *et al.*[4] and references therein). One frequency range in which particularly intense noise is observed is that lying between the plasma frequency f_p and the upper hybrid resonance (UHR) $f_{UHR} = (f_p^2+f_g^2)^{\frac{1}{2}}$ where f_g is the gyro-frequency; all frequencies refer to conditions local to the spacecraft. This is the frequency range where *Z*-mode radiation can attain very low phase velocities allowing interaction between waves and particles, and it is generally accepted that the intense noise is in the *Z* mode. Normally the noise cannot escape very far from the source region since it is reflected from the level where $X = 1+Y$ and absorbed at the level where $X = (1-Y^2)/(1-Y^2\cos^2\theta)$ where θ is the wave-normal direction. If, however, the waves propagate past the level $X = 1$, which lies between the above two levels, with their wave-normal directions close to the magnetic field direction then the coupling process between *Z* mode and ordinary mode considered by Ellis becomes operative. If, in addition, $Y > 1$ at the level $X = 1$ then another propagation window appears involving coupling between *Z*-mode and whistler-mode waves, the latter being free to propagate to the ground.

The condition that $Y > 1$ at $X = 1$ is probably met at geomagnetic latitudes $\gtrsim 70°$ for altitudes $\gtrsim 3{,}000$ km, as is apparent from Fig. 1 which is based on our present limited knowledge of the plasma-density in this region[5]. The frequencies which could be coupled are seen to be ~20 kHz–800 kHz.

It is significant that auroral hiss, which is broadband noise observed on the ground and on satellites in the geomagnetic

Fig. 1 Polar ionospheric model showing the expected radial variation of the plasma frequency f_p, the gyro frequency f_g, and the UHR frequency f_{UHR}. The region between f_p and f_{UHR} is where UHR noise from charged particle fluxes is expected. Whistler-mode noise appearing as a consequence of propagation through the second *Z*-mode window is shown shaded below the f_p curve.



latitude range 70°–80°, covers a rather similar frequency range[6]. Therefore in any computation of hiss intensities it is important to consider the possible contribution from radiation which has passed through the second Z-propagation window mentioned here.

It is clear that the process is reversible, in that upgoing whistler waves with wave normals lying within a cone centred on a certain critical direction, can be coupled to Z radiation at $X = 1$ in the topside ionosphere. The Z radiation so produced will be absorbed at the level $X = (1-Y^2)/(1-Y^2\cos^2\theta)$ where the wave energy is transferred into heat resulting in an increase in the temperature of the local plasma. Thus it may be possible to consider this process as a means of modifying the topside ionosphere by using a high power, low frequency transmitter at high latitudes.

Is the Earth expanding?

THERE have been many determinations of the acceleration of the Moon's mean longitude, mostly based on observations of occultations since 1680 and on records of ancient eclipses[1–9]. All these results have been expressed in Ephemeris Time, based on the annual apparent motion of the Sun about the Earth. Since 1955 Atomic Time came into use based on the period of oscillation of the caesium atom which is, by definition, constant. A new analysis of lunar occultations observed from 1955 to 1974 using Atomic Time, by Van Flandern (unpublished) gives a value for the acceleration of the Moon's mean longitude differing from other determinations which used the Ephemeris Time scale. His new results differ from earlier work[10]. The data reveal a difference between Ephemeris Time and Atomic Time of 25 s a century. Van Flandern suggests that the most probable explanation is a decrease in the gravitational constant, G, by 8 parts in 10^{11} per yr. Such a decrease would mean that the Earth is expanding somewhat and there is some geological evidence supporting this. We tried to check this conclusion using a method for determining the lengthening of the day verified by Wells[11] in which the number of tiny lines of ridges on well preserved epitheca of corals in their annual growth increments are counted. We found no evidence for any expansion of the Earth in the past 5×10^8 yr.

More extensive results have been published by Panella *et al.*[12] giving the number of days in the year for different geological periods. Their oldest corals are from the Cambrian, 520 Myr ago. The Table of Panella *et al.* giving the number of days, T_E, in the sidereal year has been extended by us to derive the length of the day, D, in hours and the angular rotational velocity, Ω, of the Earth. By plotting the time dependence of Ω (Fig. 1) and by assuming a linear decrease, which seems fully justified, we find a value of the time derivative

$$\dot{\Omega} = (-6.88\pm0.05)\times10^{-22}\ \text{rad s}^{-2}$$

From this it follows that

$$\dot{\Omega}/\Omega = -(29.91\pm0.05)\times10^{-11}\ \text{yr}^{-1}$$

is in excellent agreement with ref. 9.

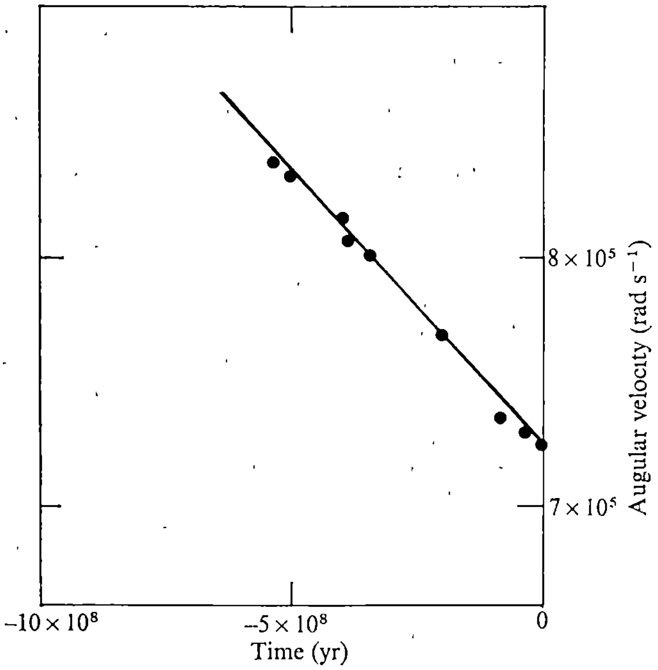

Fig. 1 The rotational velocity of the Earth derived from fossil corals during the past 540 Myr.

The total angular momentum of the Earth–Moon system is given by

$$P = C\Omega + mvr + c\omega$$

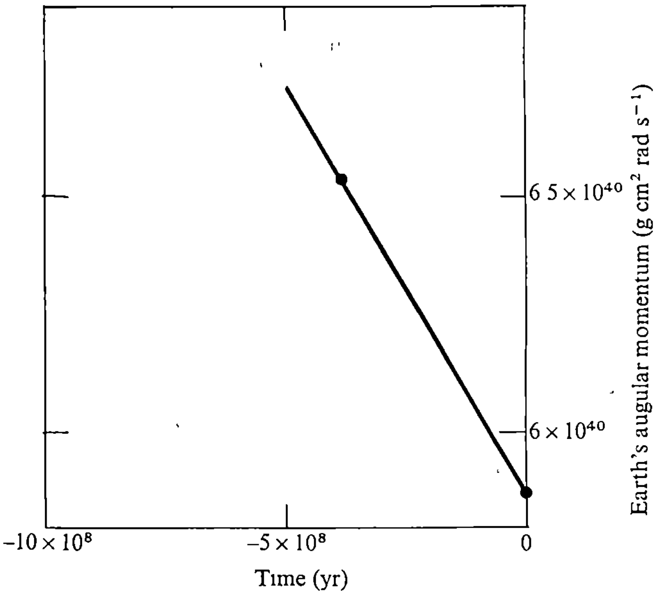
where m is the mass of the Moon, v is the linear velocity of the Moon in its orbit, r is the distance of the Moon, ω is the angular velocity of rotation of the Moon, and c is the moment of inertia of the Moon. As both $c \ll C$ and $\omega \ll \Omega$ we can ignore $c\omega$ so that

$$P \simeq P_E + P_M$$

where $P_E = C\Omega$ and $P_M = mvr = m(GMr)^{1/2}$ where M is the mass of the Earth.

As a closed system cannot lose angular momentum, the Moon must gain the angular momentum lost by the spinning Earth. If

Fig. 2 The decrease of the angular momentum of the Earth calculated by counting growth ridges in fossil corals.



we define the present angular momentum of the Earth as $P_E = 1$, the present value for the Moon is $P_M = 4.964$, and $P = 5.964$. Therefore

$$P_E = 5.964 - 4.964(r/r_0)^{1/2} \qquad (1)$$

where r_0 is the present distance of the Moon and we ignore the small variation of G.

Scrutton[13] has studied other bands between the yearly expansions found on some fossil corals and he suggested that they might reflect monthly fluctuations in growth influenced by variations in the light of the Moon. Each band contained 30.6 d and the corals investigated lived ~ 380 Myr ago in the Middle Devonian. From his 30.6 d we can calculate the length of the synodic month in hours for that time by using the length of the day, D, found in ref. 12. By using the number of days in the year we can then calculate the length of the sidereal month in the Middle Devonian and with the third law of Kepler we can easily derive from it the lunar distance r at that time.

The value of P_E in the Middle Devonian can now be found by substituting the value of r in equation (1), and from its value 6.53×10^{40} g cm^2 rad s^{-1}, plotted in Fig. 2, we derive

$$P_E = -1.76 \times 10^{40} \text{ per } 10^9 \text{ yr}$$

and

$$P_E/P_E = (-30 \pm 3) \times 10^{-11} \text{ per yr}$$

As $P_E \simeq 0.4MR^2\Omega$, where R is the radius of the Earth, we may write

$$\frac{\dot{P}_E}{P_E} = 2\frac{R}{R} + \frac{\dot{\Omega}}{\Omega}$$

The value of $\dot{\Omega}/\Omega$ derived from Fig. 1 is practically the same as the value of $\dot{P}_E/P_E$ found from Fig. 2. The conclusion seems inevitable that

$$\dot{R}/R \approx 0$$

so that the Earth has not expanded much during the past 5×10^8 yr.

An expansion of the Earth has already been pointed out by Holmes[14] and by Wesson[15] in a discussion of continental drift and seafloor spreading. If G is decreasing, the Earth should expand because of the decreased weight of the surface layers. This idea has been developed by Van Flandern (unpublished) in his discussion of the decrease of G. It would be very desirable that more extended counts on growth lines be made for fossil corals of different geological periods to check the points in Fig. 2.

Test of the dipolar nature of the geomagnetic field throughout Phanerozoic time

THE morphology of the geomagnetic field throughout the Earth's history is of interest first, in a general way, to geomagnetists in terms of long term implications concerning the Earth's core, its thermal regime and the motions in it, and, second, in a very particular way, to palaeomagnetists since the geocentric dipole model is universally used in mapping observed field directions into palaeomagnetic poles. Runcorn[1,2] has given strong reasons for supposing the mean geomagnetic field to be symmetrical about the Earth's spin axis. He has also argued[3], on the basis of early palaeomagnetic data, that a dipolar field coupled with continental motion is preferable to higher order axial multipole fields. Here I discuss an observational test, based on the much larger body of palaeomagnetic data now available, to discriminate between a dipole field and those of higher order multipoles.

Attention is restricted to the angle of inclination, I, since absolute reference meridians are not available in palaeomagnetic studies. Suppose a large number of instantaneous measurements of $|I|$ are made at randomly distributed geographical sites. For any given geomagnetic field a definite frequency distribution of $|I|$ exists, and can be obtained by simply estimating the relative surface areas of the globe corresponding to any chosen set of $|I|$ classes. For instance, a dipole field is horizontal at the equator and has $|I| = 10°$ at latitude 5.1°, whereas the field is vertical at the spin axis and has $|I| = 80°$ at latitude 70.6°. The surface areas of these two zones imply that if sampling is sufficient and geographically random we expect the $0 \leq |I| \leq 10°$ band to constitute 8.8% of the results and the $80° \leq |I| \leq 90°$ band to constitute only 5.7%. Figure 1 shows the dependence of inclination, $|I|$, on latitude, λ for the first four multipoles (dipole, quadrupole and so on) obtained from the relationship

$$\tan Il = -(1+l)Pl/(\partial Pl/\partial\theta) \qquad (1)$$

where Pl is the Legendre polynomial of degree l, and θ is the colatitude ($\theta = 90 - \lambda$). In Fig. 2 the corresponding frequency distributions of $|I|$ are given. The most notable features are the markedly low value in the range 80°–90° and the high peak in the range 60°–70° for the dipole curve.

Before comparing the palaeomagnetic data with the theoretical curves it is essential to enquire if they do, in fact, represent a random geographical sampling. Referred to the present latitude/longitude grid they clearly do not, because of uneven distribution of land and the existence of areas of relatively intense scientific effort. Throughout the past 500–600 Myr, however, considerable polar wander and/or continental drift has taken place[4,5] and we proceed on the assumption that these have been sufficient to render the palaeomagnetic sampling random in a palaeogeographical sense.

Values of $|I|$ have been compiled from the list of Hicken *et al.*[6], who feel that it is "approximately complete up to 1971". To minimise the effects of spatially and/or temporally concentrated sampling, unit weight has been given to each $10° \times 10°$ latitude/longitude square for each geological period from Cambrian to Tertiary inclusive (~ 600 to 2 Myr BP). Thus if, for example, N results are available from a certain latitude/longitude square for a particular geological period, each $|I|$ datum has been given a weight of $1/N$. Use of the geological periods is convenient and can be justified on the grounds that apparent polar wander takes place at about 0.2° Myr^{-1} and that the periods represent about 50 (±20) Myr, which implies typical within-period movement of about 10°. This is comparable with typical palaeomagnetic errors, and thus implies that a finer subdivision would be of little value.

Data from the Quaternary and the Precambrian were not included. The large body of data from the Quaternary would

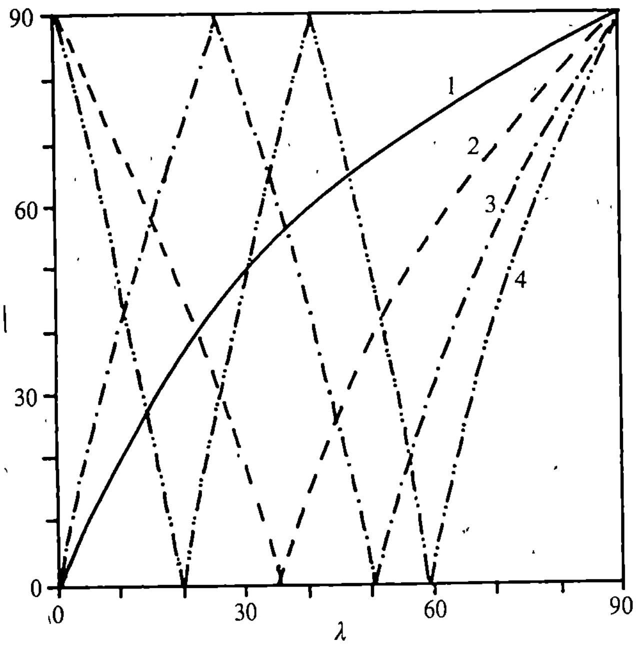

Fig. 1 Variation of angle of inclination, |*I*|, with latitude λ, for axial multipole fields. The numbers by the curves refer to the degree of the appropriate Legendre polynomial (1 = dipole; 2 = quadrupole and so on, see equation 1).

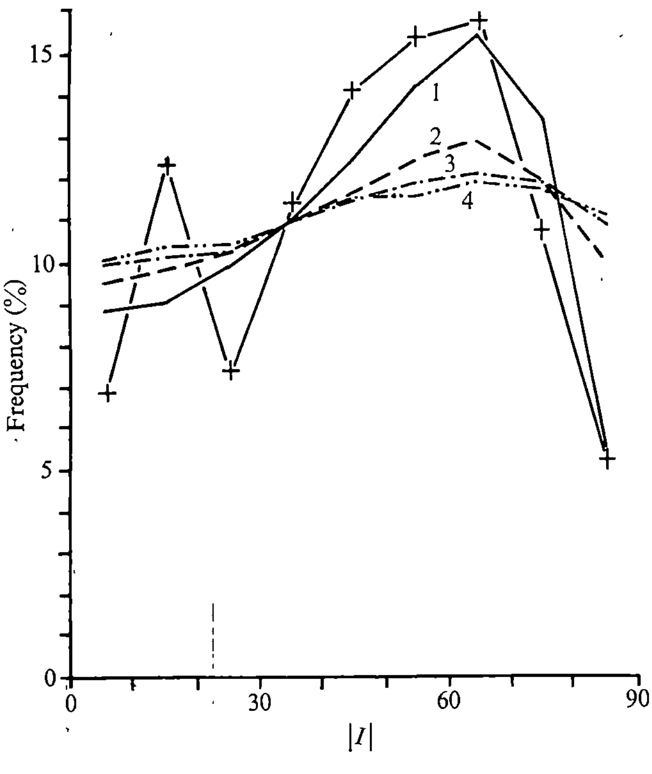
Fig. 2 Frequency polygons showing the distribution of |*I*| for axial multipole fields. The curves, and the numbers by them, correspond to the curves of Fig. 1. +, Observations.



give undue weight to the past 2 Myr that it represents and, in any case, several authors[7,8] have convincingly demonstrated the essentially dipolar nature of the field for this time interval. In the case of the Precambrian, the time involved is very long (~ 2×10^9 yr) but the data density is generally too low and is highly variable, and furthermore the assignment of accurate ages is often not feasible. For the time interval Cambrian to Tertiary the list of Hicken *et al.* yields a total of 1,271 inclination values, but the weighting procedure adopted reduces this to 430. The distribution of |*I*| is shown in Fig. 2, which indicates that the fit to the dipole curve is very reasonable, and is certainly favoured over the higher order multipoles. The main discrepancy, at low inclinations, probably reflects sampling inadequacies rather than any real feature since the total observations in the range 0–30° is 26.8% which agrees closely with the expected value of 27.7%. Another factor adding noise preferentially to a dipole model at low inclinations could be the enhanced effects of secular variations at low latitudes[9].

A χ^2 test can be used to compare the observations with the predicted distributions and yields $\chi^2 = 13.49$ for the dipole case. With eight degrees of freedom the critical value of χ^2 is 15.51 ($P = 0.05$) which indicates that we cannot assert that the two distributions differ. For $l \geq 2$ the same test strongly indicates that the observed distributions differ significantly from the expectations, χ^2 having values 27.98, 34.57, and 37.15 for $l = 2$, 3, and 4, respectively. Since palaeomagnetic errors are generally of the same magnitude as the class widths used here, it is perhaps worth while to calculate χ^2 for a coarser subdivision. Using three classes (0–30°, 30°–60°, and 60°–90°) yields $\chi^2 = 2.37$, 6.61, 8.88, and 9.98 for $l = 1$, 2, 3, and 4 respectively, compared with the critical value of 5.99 (two degrees of freedom, $P = 0.05$). Again, no difference can be claimed for the dipole case.

I conclude that the frequency distribution of palaeomagnetic inclination angles implies that the geomagnetic field has been essentially dipolar throughout Phanerozoic time.

I thank Dr M. C. Frazer for discussion and collaboration during the initial stages of this work, Mrs W. I. Gough for assistance, and Dr D. I. Gough for reading the manuscript. Financial support was received from the National Research Council of Canada.

Frequency of foreshocks

In February 1975, the Chinese Seismological Bureau successfully predicted a magnitude 7.3 earthquake near Haicheng, Liaoning Province. From their reports, it is obvious that many methods such as radon count, abnormal animal behaviour, seismic velocity, and tilt and telluric current anomalies were considered in making the long term prediction[1]. The short term prediction, however, was based primarily on foreshock activity[2,3]. That foreshocks were important in the prediction raises the question of how common they are. We here analyse the frequency of foreshocks before shallow earthquakes with magnitudes greater than 7. Our findings show that 44% of all large shallow events in the world from 1950 to 1973 had foreshocks large enough to be teleseismically recorded, and that 21% of the large earthquakes that occurred in China between 1900 and 1949 had foreshocks large enough to be noted in local records.

We used two catalogues to cover the different periods of time. We searched the catalogue of Chinese earthquakes[4] for the period 1900–49 for events preceding and near each earthquake with $M > 7.0$. Since the smallest magnitudes listed are about 4.5, and since they are listed only for the more recent portion of this period, the catalogue does not include many

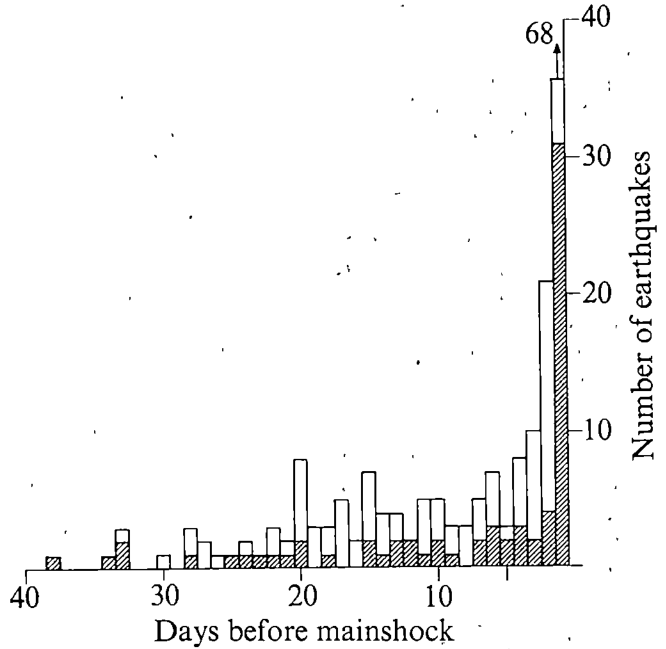

Fig. 1 Foreshock activity as a function of time before main shocks. For each day before main shocks the total number of foreshocks and the number of days before which the foreshock closest in time to the main shock (hatched area) occurred are shown.

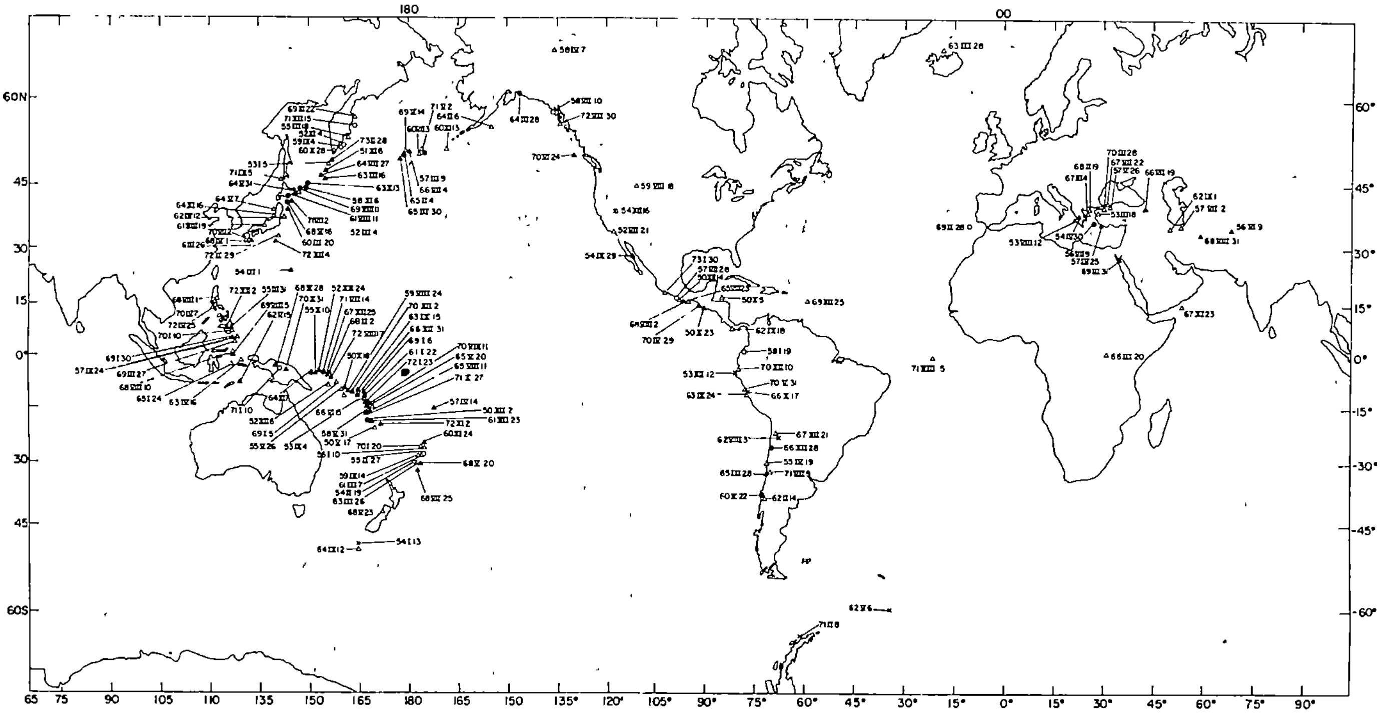
small events that would have been recorded and located with present-day instrumentation. For the period 1950–73, we searched a catalogue of world events compiled by the National Oceanic and Atmospheric Administration (NOAA) for foreshocks before all events in the world with $M > 7.0$ (1950–64)[5], and (1965–1973)[6]. The NOAA list includes all events located with teleseismic recordings by US Government agencies (Coast and Geodetic Survey, NOAA and Geological Survey) and by the Bureau Central International de Seismologique. Therefore, only events with $M \gtrsim 4$ are included. The list is complete only for events with $M \gtrsim 5$ (refs 7 and 8) for more recent years. For some periods of time and some epicentral areas the location capability was particularly low, and no relatively large foreshocks or aftershocks were located. As we were interested in how many major earthquakes were preceded by foreshocks, we decided not to include events with two or less aftershocks listed in this catalogue. Thus, of the 246 events between 1950 and 1973 with $M > 7.0$, we used only 163. In fact, of 83 events with two or less aftershocks, 7 were preceded by at least one teleseismically located foreshock.

Because the source dimensions of earthquakes with $M > 7$ are of the order of 100 km, and, because of expected inaccuracies in epicentral determinations, only events located within 100 km of the main shocks were considered to be foreshocks, even though aftershocks often occurred at greater distances from them. To be classified as a foreshock an earthquake also had to occur within 40 d of the main event. By that criterion, however, 31 of the 72 cases of foreshock activity actually occurred within 24 h of the main shocks and 58 were within two weeks (Fig. 1).

Figures 2 and 3 show the geographical distribution of the main shocks studied, and also show which had teleseismically located foreshocks. Seventy-two of 163 major earthquakes between 1950 and 1973, or 44%, had at least one foreshock in the NOAA list. Of the earlier earthquakes in China, 10 of 48, or 21%, had foreshocks. The lower value for China probably reflects a less complete record for the period 1900–49 than for more recently. In fact, Immamura[9] noted in 1937 that "big earthquakes" are preceded by foreshocks only 20% of the time, but anticipated that this percentage would increase as better instrumentation was installed.

It seems that even 44% is too low an estimate. Many earthquakes that had no foreshocks in the NOAA list (and thus not included in the 44%) are, in fact, known to have been preceded by foreshocks. For instance, Richter[10] mentioned that a foreshock occurred within 24 h of both the 1952 Kern County, California, and the 1954 Fairview Park, Nevada, earthquakes. There were 35 earthquakes in the two days before the March 1966 earthquake in the Republic of the Congo[11], a week of foreshock activity preceding the 1965 earthquake in the Ceram Sea[6], and 10 foreshocks within 24 h of the August 1, 1968 Luzon earthquake[12]. Evidently, none of these foreshocks was

Fig. 2 Map showing earthquakes with $M \geq 7.8$ (circles) and $7.0 \geq M < 7.8$ (triangles) during 1950–1973, exclusive of China, for which 3 or more aftershocks were located. Events for which at least one foreshock (closed symbols) was located and no foreshocks (open symbols) were located are shown. ×, Events with less than 2 teleseismically located aftershocks, but with foreshocks.



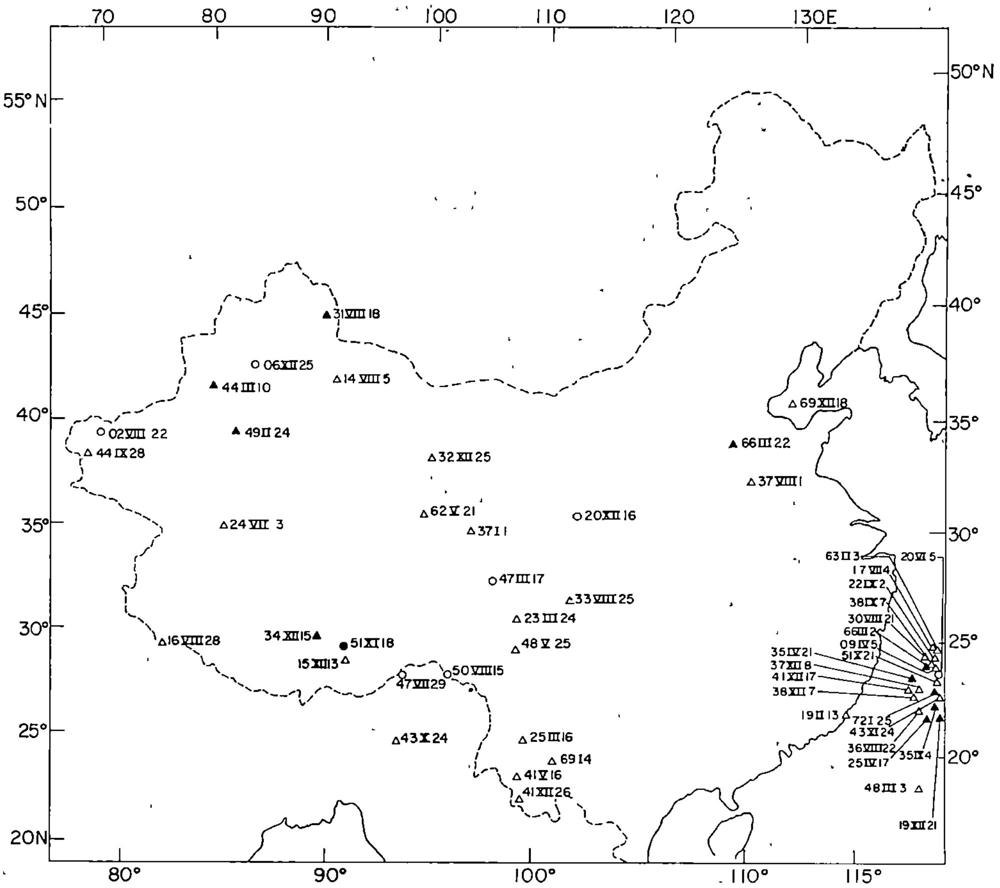


Fig. 3 Map of earthquakes in China. Symbols as in Fig. 2.

located teleseismically. Although foreshocks were the basis of the prediction of the 1975 Haicheng earthquake, none was teleseismically located by the US Geological Survey. We searched for field reports of the major events between 1950 and 1973, and found documentation of foreshocks in eight cases, for which no teleseismically located foreshocks were listed.

We sought possible correlations between the incidence of foreshocks and the magnitude or the tectonic setting of the earthquake, but no definite pattern emerged. Thirteen of the twenty-five great earthquakes ($M \geq 7.8$) had foreshocks, giving an incidence rate greater than 50%, but there are not enough data to make this conclusive.

That 44% of the earthquakes with $M \geq 7.0$ and at least three teleseismically located aftershocks were preceded by at least 1 teleseismically located foreshock suggests that foreshocks are a common occurrence. The Chinese have shown that they can be used to predict major earthquakes. The large number of locally recorded foreshocks preceding the 1965 Ceram Sea, 1966 Republic of Zaire, and 1968 Luzon earthquakes could have provided a data base comparable to that of Haicheng, and with adequate instrumentaion may have opened the door to prediction. That is not to say that all earthquakes can be predicted by foreshock activity, as there do not yet seem to be definitive methods for discriminating foreshock activity from background seismicity. Not all earthquakes, in fact, seem to be preceded by foreshocks. The February 9, 1971, San Fernando earthquake ($M = 6.6$) is an example[13]. Moreover, it is not obvious that the magnitude of an impending earthquake could be predicted by foreshocks alone.

Nevertheless, with the growing evidence of short term premonitory slip before major earthquakes[9,14–18], the frequent occurrence of foreshocks may indicate that premonitory fault slip or accelerated deformation in the focal area is a ubiquitous phenomenon preceding all major earthquakes. Indeed, the rapid increase of seismic activity before major earthquakes (Fig. 1) is similar to that of microfracturing observed in the laboratory[19]. Foreshock activity could well be the cause of many of the reports of anomalous animal behaviour. Together with aseismic deformation it could also be responsible for ground tilt, telluric current, magnetic field and well water level changes in the few days preceding major earthquakes. Thus it seems possible that all short term (and perhaps long term[18]) premonitory phenomena are a consequence of either seismic or aseismic slip before major earthquakes.

We thank W. F. Brace and F. Press for interest and encouragement. This research was supported by an Alfred P. Sloan fellowship and by the National Science Foundation.

Semiconductor liquid junction solar cells based on anodic sulphide films

ALTHOUGH good performance has been achieved with established solid state junction solar cells, their cost remains well above that required for large scale terrestrial applications. New concepts[1,2] for photovoltaic energy conversion have been introduced which involve the junction between a semiconductor and an electrolyte. These schemes may lead to new possibilities of considerably reduced materials and fabrication costs, providing that many technical problems could be solved. We report here metal–semiconductor–liquid electrolyte junctions in which an n-type sulphide semiconductor is anodically formed *in situ* on its metal and, under photoexcitation, drives a sulphide–polysulphide redox couple when connected to a suitable cathode. The original contribution in this area was made by Gerischer[2] who demonstrated that the cell (single crystal *n*-CdS/$Fe(CN)_6^{4-}$, $Fe(CN)_6^{3-}/SnO_2$) has an initial conversion efficiency > 5% (ref. 3) for sunlight to electric power, in spite of the 2.4-eV band gap of CdS, which implies that wavelengths > 550 nm (the greater part of the incident solar photons) are ineffective.

In the Gerischer cell, photoexcitation of an n-CdS single crystal causes the transfer of holes to the reduced form of the redox couple and forms the anode of the solar battery. The circuit is completed through the transparent cathode of doped SnO_2 at which $Fe(CN)_6^{3-}$ is reduced. As Gerischer has pointed out, the major problem in such a cell is that the reaction.

$$CdS+2h^+ \rightarrow Cd^{2+}+S \qquad (1)$$

competes with the desired hole injection

$$Fe(CN)_6^{-4}+h^+ \xrightarrow[CdS]{} Fe(CN)_6^{-3} \qquad (2)$$

and leads to rapid surface degradation. Such corrosion problems are inherent in most semiconductors with the exception of wide band gap materials such as n-TiO_2 used by Fujishima and Honda[1] for the photo-assisted oxidation of water.

Experience with CdS in this laboratory and elsewhere[4] has shown that the problem of poor stability can be reduced, at the expense of lowering the driving potential and thus the conversion efficiency, by using an aqueous Na_2S–Na_2S_x redox couple. The overall anode reaction

$$xS^{2-}+2(x-1)h^+ \longrightarrow S_x^{2-} \qquad (3)$$

competes more efficiently than reaction (2) with the corrosion path (1) because it proceeds at an electrode potential that is more negative by ~ 0.6 V. Additionally, any low level formation of sulphur can be prevented from covering the electrode by the dissolution reaction

$$S+S^{2-} \longrightarrow S_2^{2-} \qquad (4)$$

We show that polycrystalline CdS, anodically formed in the presence of Na_2S, can replace single crystal CdS in solar cells. The preparation of such cells is simple and inexpensive. Other metals may be used to produce sulphide semiconductors with responses into the infrared which overlap better with the spectrum of sunlight.

Electrodes were made from materials of ⩾ 99.99% purity using 10-mm sheet or cast rods of cadmium and bismuth cast from melted shot. The electrodes were defined by potting in epoxy resin. The current–voltage curves shown were obtained with rotating electrode disk configuration of active areas 0.429 cm² and 0.183 cm² for Cd and Bi, respectively. Counter-electrodes were either platinum or spectroscopic grade carbon rods. Spectra were obtained on stationary electrodes in vertical potted configurations. Potentials were measured against a standard calomel electrode (SCE).

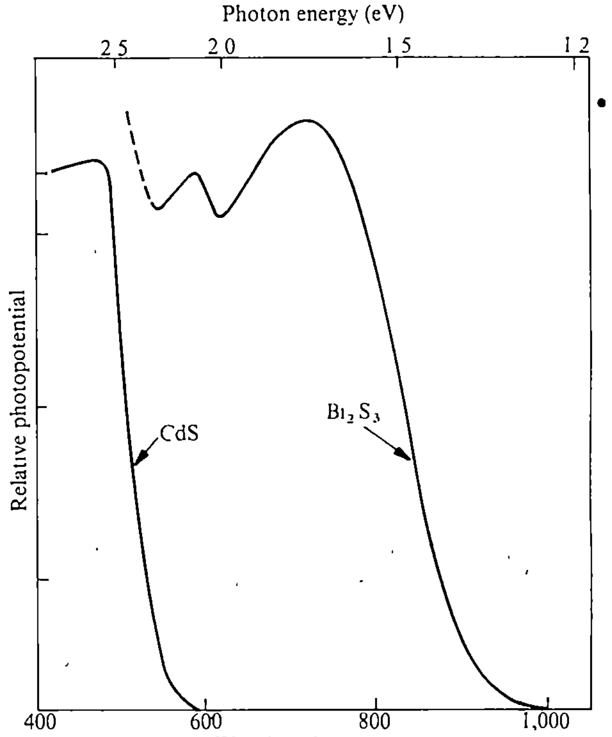

Fig. 1 Photoresponse spectra of the Cd/CdS electrode in 1F Na_2S and the Bi/Bi_2S_3 electrode in 1F Na_2S–0.05F S.

Cells with Pyrex windows at the side (vertical specimens) or the bottom (rotating disk electrodes) were used for appropriate illumination of the sample. For present purposes no attempt was made to optimise the design or electrode placement for power efficiency.

Solutions were prepared from reagent Na_2S and flowers of sulphur and were filtered before use. Spectra of the yellow polysulphide solution were obtained on a Cary 14 spectrometer.

For photoresponse spectra, electrodes were illuminated by 400-Hz chopped, monochromatic radiation obtained with a 650-W tungsten (iodine) lamp and a 1-m Spex Czerny–Turner grating monochromator. The electrochemical response was processed with a lock-in amplifier referred to the chopper frequency. A Corning 2-58 filter, which cuts off wavelengths < 6,300 Å, was used to prevent harmonic response at the higher wavelengths. The photoresponse spectra were corrected for

Fig. 2 Current–voltage characteristics of the non-illuminated and illuminated cells (*a*) Cd/CdS/Na_2S–Na_2S_x/C and (*b*) Bi/Bi_2S_3/Na_2S–Na_2S_x/C with electrolyte concentrations 1F Na_2S and 0.05F S.

monochromator throughput, light source spectrum, and solution absorbance.

The cells were activated by anodising the metal (Cd or Bi) in the Na_2S_x electrolytic solution. Anodisation could be accomplished both galvanostatically and potentiostatically. Following anodisation, the electrodes develop an opaque layer of the sulphide which, as expected, is yellowish in the case of CdS and black in the case of Bi_2S_3.

The electrochemical control circuitry used a conventional operational amplifier galvanostat–potentiostat. Photovoltaic cell operation was simulated by applying constant or linearly scanned currents in the spontaneous direction (Cd or Bi sulphides anodic) and then measuring the cell voltage (counter-electrode positive) and/or the potential of the photoelectrode against SCE which separated out any appreciable polarisation from the counterelectrode reaction. Photo-response spectra were obtained by chopping the incident beam and using as synchronously chopped output either (a) the potential relative to the counterelectrode or the SCE at open circuit or constant load current or (b) the current output when the photoelectrode was operated potentiostatically. The spectral response was found to be independent of the mode of operation or load.

The two cells considered in this work are

$$Cd/CdS/Na_2S\text{–}Na_2S_x\,(aq)/C$$

and

$$Bi/Bi_2S_3/Na_2S\text{–}Na_2S_x(aq)/C$$

The anode reaction of these cells is shown in equation (3). The cathode reaction is

$$S_x^{2-}+2(x-1)e^- \rightarrow xS^{2-} \qquad (5)$$

As noted from the sum of equations (3) and (5), there is no net chemical change in the functioning cells.

Figure 1 shows the photoresponse spectra of the n-CdS and n-Bi_2S_3 surfaces formed by anodisation in 1F Na_2S and 1F Na_2S–0.05F S respectively. As expected from the 2.4-eV band gap of CdS (ref. 5), the response of the electrode starts declining at 480 nm and becomes negligible at 580 nm. The band gap of Bi_2S_3 is ~ 1.3–1.4 eV (refs 6, 7) and the photoresponse is observed even at 900 nm, as expected. This response overlaps a substantial part of the solar spectrum after atmospheric filtering[8].

The current–voltage curves of Cd or Bi disk electrodes paired with a carbon rod cathode in very low level light and with illumination are shown in Fig. 2. The curves of both CdS and Bi_2S_3 are reasonably close to being rectangular, indicating no dominating internal resistance losses. The changes in cell voltage and the changes in the Cd or Bi potentials measured against the reference electrode (SCE) are nearly identical, and the latter are not shown. Overpotentials attributable to the carbon cathode appear to be negligible with the large cathode/anode area ratio of these cells.

The open circuit voltage of the $Cd/CdS/Na_2S\text{–}Na_2S_x/C$ solar cell under illumination is 0.59 V (see Fig. 2) or about half that reported by Gerischer[2] for the CdS (single crystal)/Fe (CN)-$_6{}^{3-,4-}$/SnO_2 system. This difference results from the higher Fermi level (redox potential) of the Gerischer solution. Sacrifice of part of the working potential leads to a cell which does not deteriorate by oxidation of surface sulphide to sulphur during operation.

It is apparent that the technique can easily be extended to other sulphides or anodic films. Considerable work remains to be done to establish whether efficiency and long term stability can be brought to levels that would make such cells practical for terrestrial solar energy conversion.

A helpful discussion with E. A. Chandross is gratefully acknowledged.

Opto-acoustic spectroscopy of products of continuous photolysis of nitromethane

THE photolysis of nitromethane has been carried out with both continuous (see ref. 1) and flash sources (see ref. 2), but for continuous photolysis no concurrent spectroscopy has been reported. This is in general true of most photolysis experiments, since the steady-state concentration of intermediates produced by continuous sources is usually insufficient to record spectra without depending on some matrix isolation procedure. We report here on gas phase continuous wave photolysis experiments using opto-acoustic detection of the energy absorbed by intermediates from a continuous wave (CW) tunable dye laser[3]. This allowed the detection of intermediate concentrations of ~ 10^{13} mol cm^{-3}. Opto-acoustic detection was discovered by Bell[4] nearly a century ago, but was recently revived as a means of monitoring low concentrations of pollutant molecules[5,6]. In our experiments the intermediates act as the 'pollutant' molecules to be detected.

The reaction vessel was a 5-cm long block of stainless steel through which a channel 0.5 cm × 1.0 cm had been cut. This channel was connected to a sidearm containing a sensitive microphone and to a small reservoir containing the sample. Two quartz windows sealed the ends of the channel. The unchopped and unfiltered output from a 250-W medium pressure Hg lamp was focused down to pass through the channel from one end. Tunable CW dye laser radiation, chopped at ~ 1.4 kHz, passed through the cell in the opposite direction. If the incoming chopped radiation is absorbed by a constituent in the cell that part of the absorbed energy degraded to heat will, in a constant volume enclosure, set up a modulated pressure wave at 1.4 kHz detected by the microphone.

Previous experiments[2] on pure nitromethane yielded evidence of nitroxyl and formaldehyde production together with OH and CN radicals. Neither nitrogen dioxide nor nitrosomethane were detected in these conditions, whereas they had been detected in the presence of excess nitrogen. Since the primary process is most probably

$$CH_3NO_2 \rightarrow CH_3+NO_2 \qquad (1)$$

NO_2 at least should be formed in the photolysis of pure CH_3NO_2, and indeed was detected by electron paramagnetic resonance (EPR) measurements[7].

Figure 1*a* shows the opto-acoustic spectrum between 580 and 610 nm obtained from a sample of pure nitromethane at a temperature of 50 °C (pressure ~ 90 mmHg) under continuous photolysis. It was confirmed that, before photolysis commenced, no signal in this wavelength region existed. The spectrum of Fig. 1*a* thus corresponds to a species created by the photolysis. Figure 1*b* shows the spectrum obtained on buffering the nitromethane with 275 mmHg of argon and Fig. 1*c* using 275 mmHg

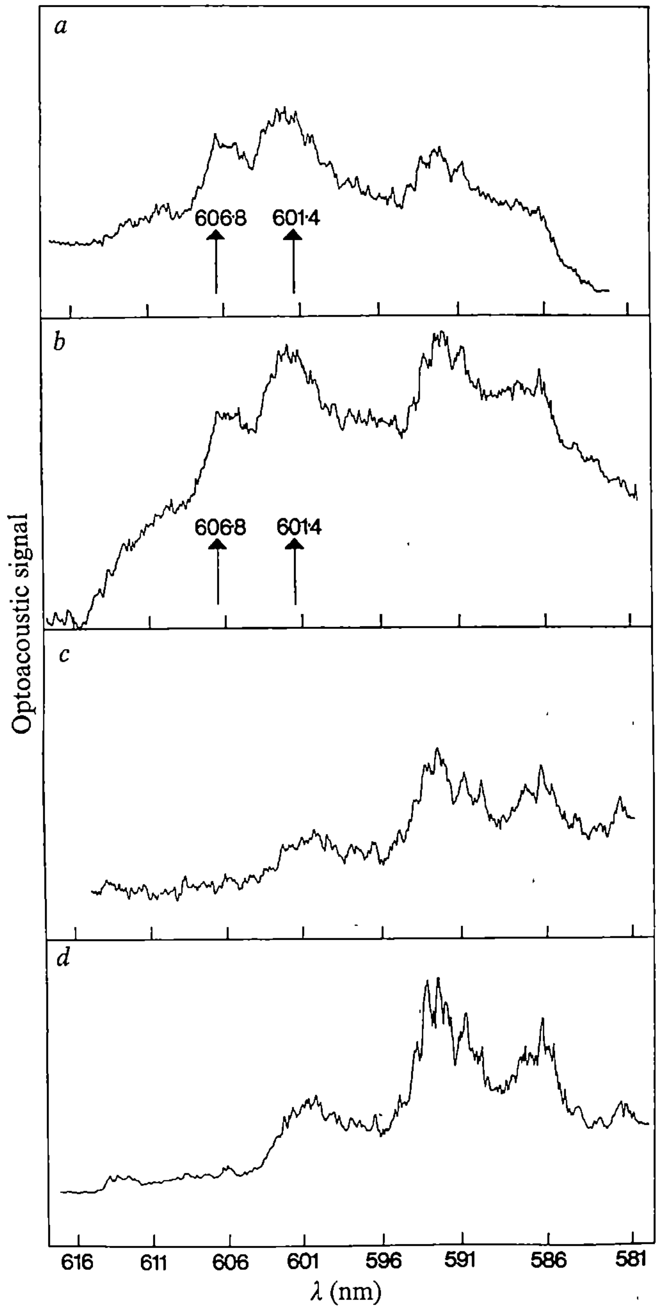

Fig. 1 Opto-acoustic spectra of CH_3NO_2 during continuous photolysis: *a*, pure CH_3NO_2; *b*, CH_3NO_2 in 275 mmHg argon; *c*, CH_3NO_2 in 275 mmHg oxygen; *d*, Opto-acoustic spectrum of 3×10^{-4} mmHg NO_2 in 300 mmHg N_2. (The spectra are uncorrected for the smooth variation in dye laser power output over its tuning range.)

of oxygen as a buffer. For comparison we show the spectrum of NO_2 taken in the same cell (but without the photolysis lamp) at ~ 3×10^{-4} mmHg in 300 mmHg of N_2. It is evident from a comparison of the spectral features ~ 586 and 590 nm that we are recording the presence of NO_2 at levels ~ 10^{-4} mmHg during the photolysis of nitromethane. The additional features at 607 and 610 nm disappear when oxygen is used as a buffer (Fig. 1*c*) leaving the pure NO_2 spectrum. The spectrum towards longer wavelengths of this second product is shown in Fig. 2, again from the photolysis of CH_3NO_2 in argon at 50 °C. From the positions of the band centres by comparison with those given by Dixon and Kroto[8] we can identify this product as nitrosomethane. It was confirmed in a separate experiment that NO_2 absorption in this region and at the concentrations inferred from Fig. 1*c* was not contributing >10% to the observed signal. In addition, its spectrum is markedly different to that of the nitrosomethane. We conclude that the spectrum of Fig. 2 is that of CH_3NO and that the features on the long wavelength end of the NO_2 spectrum of Fig. 1*a* and *b* come from the tail of CH_3NO absorption.

The build up of both CH_3NO and NO_2 on initial exposure took the same time of ~ 10 s. Similarly, the decay, a non-exponential with a fast initial fall changing gradually to give a long tail lasting ~ 20 min, was the same for both products. This decay behaviour was very different when O_2 was used as a buffer. In this case the NO_2 signal initially increased by ~ 20% and then followed a slower decay of up to ~ 30 min.

These results are consistent with the following set of secondary reactions following the primary split 1.

$$CH_3+NO_2 \rightarrow CH_3O+NO \quad (2)$$
$$CH_3+NO \rightarrow CH_3NO \quad (3)$$
$$NO_2 \xrightarrow{h\nu} NO+O \quad (4)$$
$$CH_3+NO_2 \rightarrow CH_3NO_2 \quad (5)$$
$$CH_3NO+NO_2 \rightarrow CH_3NO_2+NO \quad (6)$$
$$CH_3O+NO_2 \rightarrow CH_3ONO_2 \quad (7)$$

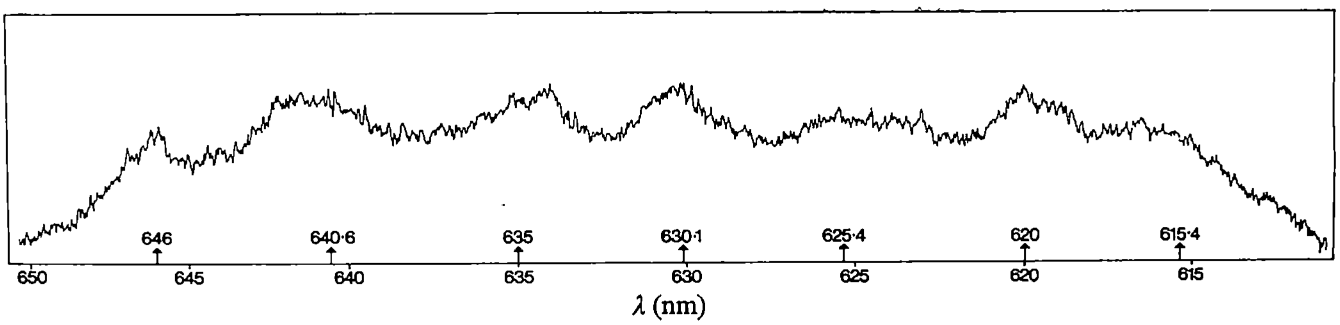
It is clear that in our relatively cool photolysis conditions and low intermediate concentrations (2) and (4) produce enough NO to yield measurable quantities of CH_3NO, whereas in the flash photolysis of Napier and Norrish[2] added amounts of NO were required before CH_3NO was detected. The alternative reaction[2]

$$CH_3O+NO \rightarrow HNO+CH_2O \quad (8)$$

is presumably less efficient than reaction (3). (We did not observe nitroxyl formation but, since its spectrum[9] would be partially obscured by nitrosomethane, we do not rule out its formation.)

Reaction (6) (ref. 10) accounts for the identical bimolecular decay nature of NO_2 and CH_3NO although at some stage reaction (7) and the formation of nitrosomethane dimers become important[2]. The change in decay behaviour of the NO_2 in the

Fig. 2 Opto-acoustic spectrum (620–650 nm) of CH_3NO_2 in 275 mmHg of argon during continuous photolysis. Arrows mark the positions of band centres assigned to nitrosomethane (from Dixon and Kroto[8]).



O_2 mixtures, that is, without CH_3NO formed, is strong evidence for the influence of reaction (6). With O_2, CH_3NO formation is quenched, presumably by

$$2CH_3+O_2 \rightarrow 2CH_3O \qquad (9)$$

or similar processes, and

$$CH_3NO+O_2 \rightarrow CH_3ONO_2 \qquad (10)$$

and the decay of NO_2 governed solely by reaction (7). The rise in the NO_2 signal on removing the photolysing source probably arises from recombination of excess NO with oxygen.

We are indebted to Dr J. Pfab for helpful discussions. This research was supported by the SRC.

New light on the skull anatomy and systematic position of *Oviraptor*

Oviraptor philoceratops Osborn, 1924—a plunderer allegedly fond of ceratopsian eggs—is an Upper Cretaceous vertebrate assigned to the theropod dinosaurs[1]. The holotype, comprising a compressed skull with mandibles, several cervical vertebrae, fragmentary shoulder girdle and forelimbs, was found in the Djadokhta Formation (?Santonian), Gobi Desert, Mongolia. For many years this was the only specimen known and its poor preservation showed only that *Oviraptor* was a toothless bipedal animal, with a lightly built skull, unusually short and deep. The lack of teeth and the structure of the manus were the main arguments for assigning it to the family Ornithomimidae[1,2].

In 1970 and 1971 the Polish–Mongolian palaeontological expeditions to Mongolia found two skulls (Fig. 1) of *Oviraptor* sp. with a few postcranial fragments in the Khermeen Tsav Formation (?Middle Campanian) as well as a fragmentary skull in the Nemegt Formation (?Upper Campanian—? Lower Maastrichtian), all in the Gobi Desert[3]. This material is housed in the Zaklad Paleozoologii (ZPAL) in Warsaw and I am now studying it. Five skeletons with skulls of *Oviraptor* sp. were found in 1972 by the Soviet–Mongolian palaeontological expeditions in the Khermeen Tsav formation[4]. This latter material is being studied by Dr R. Barsbold (Institute of Geological Sciences, Ulan Bator). All the specimens found recently belong to a new species. As the material being investigated by Barsbold is more complete than that at my disposal, I leave him to name and diagnose the new species, referring here to the forms housed in Warsaw as *Oviraptor* sp.

In the light of this new material the systematic assignment of *Oviraptor* may be questioned. The structure of the palate (Fig. 1*e*, *f*) is completely different from the palate of all other known dinosaurs. Its most striking feature is the form of the pterygoids. They are massive bars, with their lateral portions turned strongly ventrad. The ectopterygoids, which in all other dinosaurs are directed transversely, joining the pterygoids with the jugal arches, lie parasagittaly in *Oviraptor* and join the ptergoids with the maxillae, medial to the anterior roots of the jugal arches. Such a pterygoid–ectopterygoid structure is highly convergent with the dicynodont reptiles. The same may be said of the anterior palatal region formed of the premaxillae and maxillae, which bears a pair of ridges along its medial portion. Each maxilla in *Oviraptor* sp. produces a 'tooth' posteriorly, which is directed ventrally (Fig. 1*a*, *b*) and lies very close to its fellow. These 'teeth' are buttressed posteriorly by the thickened vomer. They do not bear any trace of wear and were therefore evidently covered in by a horny or soft tissue. The position of the palatine bones in *Oviraptor* is also different from that in other dinosaurs. The medial wings of the palatines border the choanae posteriorly, but laterally they form the ventral links between the maxillae and the ectopterygoids in a manner never seen in other dinosaurs.

Another unusual feature in a dinosaur is the very strong pneumatisation of the skull bones, especially those of the roof and snout. The nasals, in addition to being pneumatised as a whole, each bear a large air chamber connected with the external nare.

The endocranial cavity is well exposed on the two skulls I have studied, and is unusually large for a dinosaur, relative to the size of the skull. The approximate length of the cavity of the skull ZPAL No. Mg-I/95, measured from the foramen magnum to the dorsal border of the exit of the optic nerve, is 40 mm; its height (at the level of the optic nerve) is 17 mm; and its maximal width (just in front of the optic nerve) is 27 mm. The length of the skull is only 98 mm. The rapid broadening of the endocranial cast in front of the optic lobes is very striking, and corresponds to the position of the cerebral hemispheres, its total width almost double that of the diencephalon. The olfactory tracts must have been very short, as judged from the preserved portion of the endocranial cavity and from the close position of the external nares. Such a structure in the olfactory part of the brain seems to be non-dinosaurian and even non-reptilian (pterosaurs excluded).

The structure of the mandible of *Oviraptor* is also very different from that of other dinosaurs, and it was investigated in detail using the new material housed in Warsaw. The *Oviraptor* mandible (Fig. 1*g*, *h*) is basically similar to those described as *Caenagnathus collinsi* Sternberg, 1940 (ref. 5) and *C. sternbergi* Cracraft, 1971 (ref. 6) and assigned to the birds. The mandibles of *Caenagnathus* and *Oviraptor* have a similar shape, the same relationships between the bones and an identical articular region, consisting of a low ridge directed anteroposteriorly. They differ mainly in their proportions. Cracraft[6] noticed that the jaw of *Caenagnathus* is structurally convergent with that of the dicynodonts; and this is in perfect agreement with my study of the skull of *Oviraptor*. *Oviraptor* and *Caenagnathus* should thus be assigned to the same family, Caenagnathidae Sternberg[5].

Should the Caenagnathidae, however, be considered as birds? It is hardly possible that they are birds, taking into account the fact that known forelimbs of *O. philoceratops* do not show any distinct avian adaptations. In fact, the manus structure of this animal, with its three clawed digits subequal in length, conforms to that of the ornithomimids. The generally saurischian and theropod postcranial skeleton (confirmed by the Soviet–Mongolian expeditions; R. Barsbold, personal communication) may be evidence that, in spite of all the differences mentioned here, the Caenagnathidae should be regarded as theropod dinosaurs. Their skull structure is so peculiar, however, that long independent evolution of the group must be presumed. The caenagnathids may represent a Cretaceous continuation of the same dinosaur lineage that gave rise to the birds[7]. This could

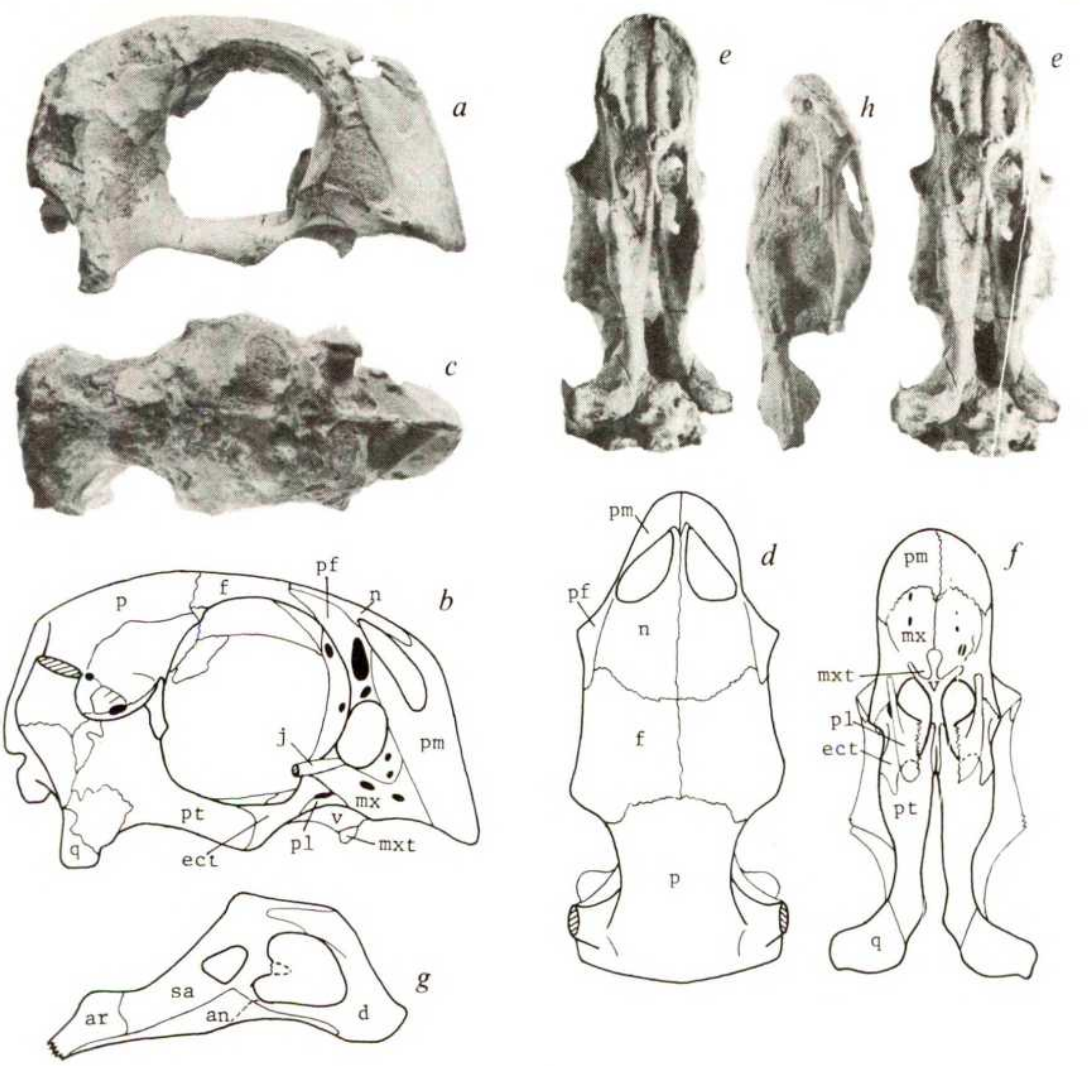

Fig. 1 *Oviraptor* sp. ZPAL No. MgD-I/95 skull lacking temporal and jugal arches: *a*, *b*, lateral view; *c*, *d*, top view; *e*, stereophotograph, palatal view; *f*, palatal view; *g*, mandible of the same specimen, lateral view; *h*, ventral view (approx. ×0.59). an, Angular; ar, articular; d, dentary; ect, ectopterygoid; f, frontal; j, jugal; mx, maxilla; mxt, maxillary 'tooth'; n, nasal; p, parietal; pf, prefrontal; pl, palatine; pm, premaxilla; pt, pterygoid; q, quadrate; sa, surangular; v, vomer.

explain the presence of some para-avian characters in the caenagnathid skull, such as the separation of the pterygopalatine complex from the jugal arch, the pneumatisation of the skull, the possible enlargement of the brain with the simultaneous shortening of the olfactory tracts and some structural characteristics of the mandibles. For these reasons it is not possible to assign the Caenagnathidae to any of the known theropod infraorders. A new suprafamilial taxon will have to be established as soon as the new material of *Oviraptor* has been described.

Hallucial tarsometatarsal joint in an Oligocene anthropoid *Aegyptopithecus zeuxis*

SINCE the grasping hallux is such a significant characteristic of the order Primates, its evolutionary history is of some importance to palaeoprimatologists. Although the origin and development of the grasping hallux in primates is usually hailed as a major "evolutionary event", very little factual data from the palaeontological record can be brought to bear in documenting this feature throughout primate evolution[1]. Two fossil primates in which an hallucial metatarsal is known are *Notharctus* (an Eocene prosimian) and *Dryopithecus africanus* (a Miocene hominoid); hence the specimen discussed here is the earliest document of hallucial morphology in the anthropoids[2,3].

The earliest known postcranial remains of fossil anthropoids are from the Oligocene Jebel el Qatrani Formation of the Fayum badlands, Egypt. Most of the primate skeletal remains have been referred to the parapithecid *Apidium phiomense*; one ulna has been referred to *Aegyptopithecus zeuxis*[4,5]. Included among the various mammalian postcranial remains is an hallucial metatarsal of an anthropoid primate which was discovered by E. L. Simons at Yale

Quarry I in the Upper Fossil Wood zone. This is the quarry that has yielded mandibular and/or maxillary dental remains of several primate genera—*Parapithecus, Apidium, Aeolopithecus* and *Aegyptopithecus*[6]. Of these fossil primates, only *Aegyptopithecus* could have had a hallax as large as that suggested by the fossil hallucial metatarsal. For this reason the specimen is here referred to *Aegyptopithecus zeuxis.*

The specimen (YPM 25806) consists of the proximal two-thirds of a right hallucial metatarsal (Fig. 1). The bone is perfectly preserved except for a small sliver missing from its medial side. The proximal articular surface for the medial cuneiform is complete and undistorted. Its overall size suggests an animal whose body weight might be approximated by *Ateles belzebuth* (Fig. 2).

fig 1

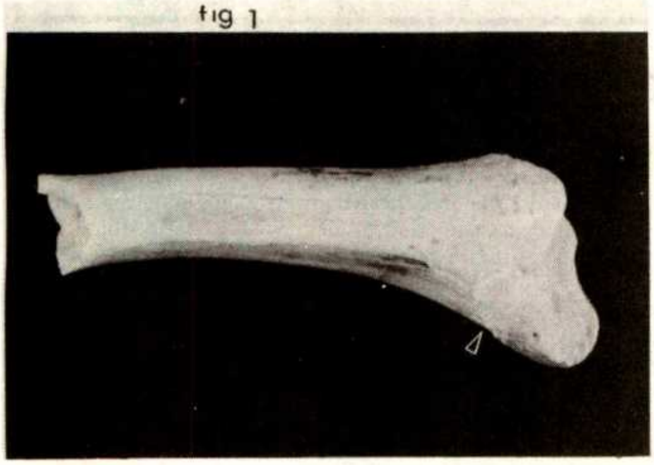

Fig. 1 Medial view of right hallucial metatarsal of *Aegyptopithecus zeuxis* (YPM 25806). Note prehallucial facet (arrow).

Much information concerning the morphology of the primitive anthropoid hallucial tarsometatarsal point can be gathered through examination of the proximal articular surface of the hallucial metatarsal of *Aegyptopithecus zeuxis.* Of particular interest is a well defined, raised oval facet on the medioplantar aspect at the base of the metatarsal. This undoubtedly reflects the fact that a large prehallux bone participated in the hallucial tarsometatarsal joint. Thus, this joint consisted of three bones in primitive anthropoids, the first metatarsal, medial cuneiform and prehallux. This condition is unlike that of any extant Old World monkey or great ape; it is seen in most platyrrhines and hylobatids[7]. On the lateral plantar aspect of the metatarsal base is a large, blunt, bony projection for the insertion of M. peroneus longus tendon. This muscle, an everter of the tarsus and an adductor of the hallux, was obviously large in this primitive, arboreal fossil ape. In contrast, *Simopithecus,* a large, terrestrially adapted Pleistocene monkey, had a rather small peroneus longus muscle. This is evidenced by the relatively small peroneal tubercle and the small facet for the peroneus longus sesamoid on the cuboid[8]. The Fayum metatarsal also has a rather pronounced longitudinal curvature, indicative of strong flexor tendons[9].

fig 2

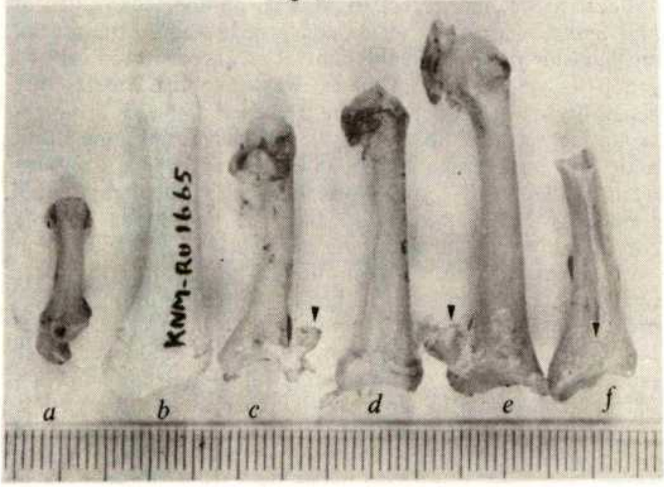

Fig. 2 Comparison of hallucial metatarsals of several primates. *a, Galago crassicaudatus; b, Dryopithecus africanus; c, Cebus nigrivittatus; d, Hylobates hooloch; e, Ateles belzebuth; f,* YPM 25806. Note the attached prehallux in *Cebus* and *Ateles* and prehallucial facet on YPM 25806 (arrows).

The shape of the joint surface itself, for articulation with the medial cuneiform, is essentially a concave ovoid with a nearly vertical axis around which abduction–adduction took place (Fig. 3). The ovoid widens in a plantar direction, thus producing an effect where the plantar surface of the metatarsal rotates around a greater arc than the dorsal surface. Because any point which traverses an arc along an ovoid surface will undergo conjunct rotation, this morphology is advantageous in any joint where opposition is desirable[10]. Thus, as the metatarsal moves over the articular surface of the medial cuneiform it undergoes conjunct rotation and comes more into opposition with the lateral four digits. The prehallux would have completed the joint surface at the medioplantar border. The dorsal and lateral margins of the metatarsal base show rugosities for tarsometatarsal ligaments. During adduction of the hallux, the plantar surface of the bone would have been oriented towards the lateral digits as in opposition. This is due to the morphology of the joint surface itself (see above) and to the fact that the shaft of the metatarsal shows a high degree of torsion in this direction. This torsion is evidenced by the fact that the greatest diameter of the shaft in cross section is nearly parallel to the vertical axis of the hallucial base.

fig 3

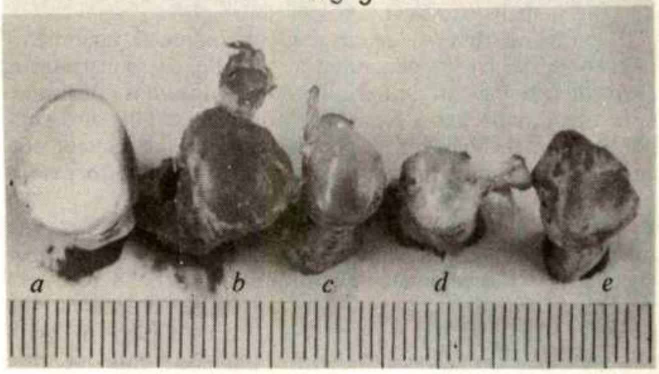

Fig. 3 View of proximal articular surface of hallucial metatarsals. *a, Dryopithecus africanus; b, Ateles belzebuth; c, Hylobates hoolock; d, Cebus nigrivattatus; e,* YPM 25806.

Lewis has described the hallucial tarsometatarsal joint in anthropoids, and his predictions concerning the morphology of the hallucial tarsometatarsal joint in primitive anthropoids can be verified by the fossil evidence presented here[7]. He has shown that in primitive mammals (for example, *Didelphis*) an hallucial prolongation of the flexor tibialis muscle (the homologue of the M. flexor digitorum longus in the human) contains the prehallux. When the prehallux occurs in primates it forms an integral part of the hallucial tarsometatarsal joint and is invariably associated with the dual insertion of tibialis anterior into it and the medial cuneiform. The prehallux, judging from the shape of its articular facet on the hallucial metatarsal of *A. zeuxis,* had a sellar-shaped articular surface and formed part of a true synovial joint, as do most sesamoid bones in the body. Sellar-shaped surfaces are characteristic of joints which have opposition as a habitual movement[10]. The prehallux, or a cartilagenous remnant, is characteristic of

Ceboidea but not Ceropithecoidea. Among Hominoidea, it is seen in Hylobatidae but not Pongidae[7].

It is perhaps interesting that a vestigial prehallux is occasionally found in modern man[11-13]. The so-called "os paracuneiforme" was first described clinically in 1902 (ref. 14). Although surgeons were unsure of what this small accessory bone really represented, evidence now suggests that it is the vestige of the primitive anthropoid prehallux (my unpublished results). The "os paracuneiforme", like the prehallux, articulates with the medial cuneiform and is protected by an overlying bursa; as in anthropoids, the bone is partly incorporated in the substance of the tibialis anterior tendon. It is still unclear whether or not this is a true accessory bone or a sesamoid[15]. Alternatively, it might represent one of the unfused multiple ossification centres in the epiphysis of the metatarsal[16]. It seems most likely, however, that it is a sesamoid formed by pressure in the tendon of tibialis anterior as it passes over the medial cuneiform; indeed, such bones sometimes occur late in life in this position[17]. Experimental evidence on the patella, the largest sesamoid in the body, suggests that both phylogenetic and ontogenetic factors are responsible for the formation of sesamoid bones. For example, development of the patella has followed transplantation of limb bud fragments from chick embryos to the chorioallantoic membrane of other host embryos[18]. Conversely, patellar cartilage and bone which has been removed from young dogs will regenerate from young connective tissue cells which had not been destined as specific formers of bone if the tendon of the quadriceps femoris is sutured to the patellar ligament and the joint is exercised[19].

The finding that *A. zeuxis* had an hallucial tarsometatarsal joint which incorporated a prehallux demonstrates a clear morphological similarity between this most primitive anthropoid and extant New World primates. This also supports recent evidence that the postcranial skeleton of the earliest anthropoids in general was more similar to extant platyrrhines than to catarrhines[4,20].

The morphological similarities between the Oligocene primates of the Fayum and extant platyrrhines have led to speculations regarding an African origin for the New World primates through rafting across the South Atlantic in the early Tertiary. Such a voyage seems hard to reconcile with the geophysical evidence suggesting that the South Atlantic was 3,000 km wide by Oligocene times[21]. Others have suggested that some primate family with a holarctic distribution in the Eocene (Adapidae?) might have given rise to both New and Old World anthropoids by the early Oligocene[22]. One point is becoming increasingly clear however—platyrrhines are the best models for depicting the earliest stages of anthropoid postcranial and locomotor evolution. Lewis' contention that the earliest anthropoids must have possessed an hallucial tarsometatarsal joint including a prehallux is undoubtedly correct. It is interesting that *Dryopithecus africanus*, a putative descendant of *A. zeuxis*, also apparently had a prehallux incorporated into its hallucial tarsometatarsal joint[7]. Thus there is nothing in the anatomy of the hallucial tarsometatarsal joint which would preclude *Aegyptopithecus* from being broadly ancestral to later dryopithecines and hylobatids.

I thank Professor E. L. Simons for permission to study fossils collected by his expeditions to the Fayum and Professors C. Jolly and M. Schon for comments on the manuscript.

Control of intragroup aggression by male pigtail monkeys *(Macaca nemestrina)*

CERCOPITHECINE primates (*Macaca, Papio,* and *Cercocebus* spp.) typically live in cohesive groups containing many more adult females than adult males. Strong status hierarchies often exist within established groups, and one male in each group usually exerts an especially powerful influence on the behaviour of other group members. This individual commonly places himself between the group and any potential external threat and frequently interferes in intragroup aggressive encounters by attacking or threatening to attack one of the participants in the altercation[1]. An animal displaying this pattern of behaviour has been referred to as a "control animal" or as fulfilling a "control role"[2].

While the existence of such a control role has been generally accepted, most descriptions of this behaviour have not measured the magnitude of the influence of male presence on the inhibition of violence among females. Cessation of aggression contiguous with attacks or threats by males has provided the bulk of evidence for control role behaviour. In one experimental study, however, removal of the control male from a group of pigtail macaques (*M. nemestrina*) resulted in increased aggression among other group members and his reinstatement in the group reduced aggression to preseparation level[3]. The removal and reinstatement of other group members did not influence intragroup aggression. Unfortunately that experiment used only one group of monkeys under one set of housing conditions, a situation hardly sufficient to establish the generality of the phenomenon.

Because we had access to a large number of groups of *M. nemestrina* and were concerned about the social mechanisms involved in the control of aggression in captive groups of non-human primates, we felt obliged to test the generality of the effect of mere presence of males on intragroup aggression. Six groups, each containing one adult male and an average of 8.5 adult females and 1.1 infants were studied. Each group was housed in identical spatial conditions (2.2×3.1×2.8 m), but the conditions differed considerably from those of the previously cited experiment. Each group was tested according to a sequence of three phases (each 20 min long): a pretest with all group members present to establish basal aggression rates; an experimental test immediately following removal of the male from each group; and a post-test immediately following reintroduction of the male into the group. An experienced observer recorded absolute frequencies of agonistic interactions of group members, noting the sex of the perpetrator and recipient of each act. The following activities were recorded: contact aggression (grab, push, hit, and bite); non-contact aggression (chase, open-mouth "threat", and "bark" vocalisation); and submission (grimace, "screech" vocalisation, and crouch).

eproductive correlates ova emissions by baboons

species of rodents, the social and reproductive f a host individual has been shown to affect its ...y to intestinal parasites and the maturation rate of sites once established[1,2]. The relationship between nd reproductive condition of host individuals and aspects of parasite development and transmission, in-ding ova emissions, has not previously been examined for y non-human primate species. Information on parasite ova emissions by non-human primates is important for understanding the life-cycle of the parasites and for understanding the spread of parasites both within and between social groups and to individuals of other species, including humans and domestic stock[3].

In 1974, as part of an ongoing longitudinal study of free-living yellow baboons (*Papio cynocephalus*) in the Amboseli National Park, Kenya, we collected 100 faecal samples from the 29 adult and subadult members of a single well studied group[4]. Intestinal parasite ova were recovered from these samples by zinc sulphate flotation[5] and number of ova per g of faeces was analysed in relation to dominance rank and reproductive condition of host. Egg recovery and counting was done "blind"; samples were identified only by a sequence number and not by name or other information concerning the host. Two nematode genera, *Trichuris* and *Trichostrongylus* accounted for 89% ($N = 2{,}119$) of all parasite ova recovered in the samples. The distribution of number of ova per g of faeces for all samples combined was positively skewed and roughly Poisson in shape; thus, significance testing was carried out with the variance ratio[6].

Figure 1 shows that among adult and subadult males, high ranking individuals had higher egg emissions than did more subordinate individuals. All differences in mean egg counts between adjacent dominance rank classes were statistically significant ($P < 0.01$ for all comparisons); the Spearman rank correlation coefficient between mean egg count and dominance rank in adult and subadult males was 0.67 ($P < 0.05$). Subadult males generally had lower egg counts than did older, fully adult males, and ranks 13–16 were occupied exclusively by subadults. But, examination of the mean egg counts for ranks 1–12 alone, which eliminated the age-related low egg counts of subadults, still showed a strong correlation between mean egg output and dominance rank in adult males ($r_s = 0.56$, $P < 0.05$). Since adult male baboons change rank frequently[4], Fig. 1 is based only on samples collected when adult males were stable, or consistent, in their dominance relationships. Egg output by adult males during periods of inconsistency was usually lower than egg output before the period of inconsistency, but only a small number of such samples were obtained.

The mean egg count for adult females, 26.58 ova per g, was significantly higher than the mean egg count for adult males during periods of rank stability, 20.69 ova per g ($F_{max} = 1.28$, d.f. = 2,552, 1,490, $P < 0.01$), and this difference was even greater when subadult males and adult males inconsistent in their dominance relationships were included in the comparison. Parasite ova emissions among adult females, however, were not correlated with dominance rank ($r_s = 0.02$, $P > 0.05$), although middle ranking females did have significantly higher egg counts than did low ranking females ($F_{max} = 1.24$, d.f. = 1,054, 714, $P < 0.01$) (Fig. 1).

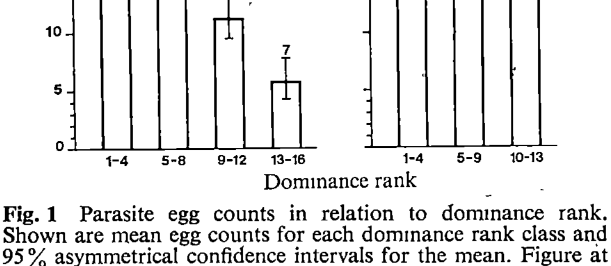

Fig. 1 Parasite egg counts in relation to dominance rank. Shown are mean egg counts for each dominance rank class and 95% asymmetrical confidence intervals for the mean. Figure at top of each bar gives number of samples on which mean is based. For adult males, analysis included only samples collected during periods of rank stability. Subadult males are the same age as young adult females.

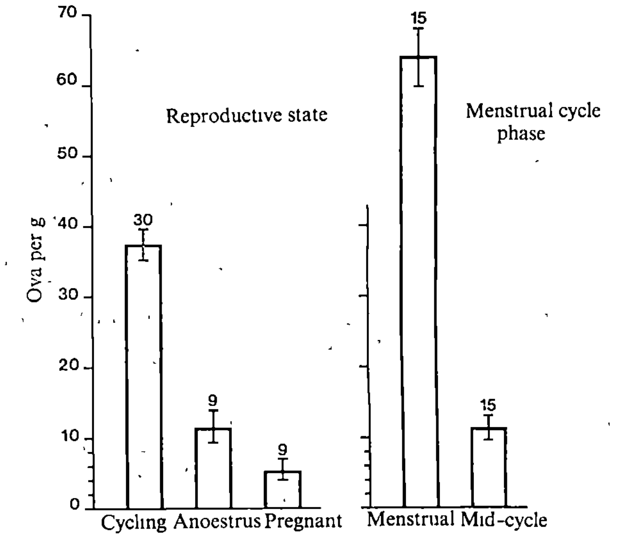

Fig. 2 Parasite egg emissions in relation to female reproductive state and menstrual cycle phase. Conventions as in Fig. 1.

Adult female baboons rarely change dominance rank, but changes in their reproductive state or menstrual cycle phase occur frequently[4]. Sexually cycling females had significantly higher egg emissions than did anoestrous (lactating or otherwise non-cycling) females ($F_{max} = 3.26$, d.f. = 2,250, 206, $P < 0.01$); anoestrous females in turn had significantly higher egg emissions than did pregnant females ($F_{max} = 2.14$, d.f. = 206, 96, $P < 0.01$) (Fig. 2). Among sexually cycling females, mean egg counts were significantly higher during the one week immediately before and the one week immediately after the onset of menstruation compared with the remaining 3 weeks mid-cycle that include oestrus and ovulation ($F_{max} = 5.65$, d.f. = 1,912, 338, $P < 0.01$) (Fig. 2).

One simple but plausible explanation for the observed pattern of parasite ova emissions is that individuals differ in ingestion rate of infective and non-infective ova or in other aspects of food intake, gut passage time or faecal output. Alternatively, high ranking adult males and sexually cycling females may provide a generally more favourable internal environment for egg production by parasites than do individuals of other social and reproductive classes. Of course, the above correlations might also reflect actual differences in the burden of adult worms harboured by individuals of each social and reproductive class. Although unlikely, it is also possible that parasite ova emissions affect social and reproductive condition, for example, dominance rank, rather than the other way around as presumed by the above alternatives. Regardless of their precise explanation, the relationships described in this note, if substantiated by more extensive studies, will be of interest and importance to many scientists concerned with primates, parasites or public health.

Support of this research by the NSF, research clearance from the government of Kenya and the cooperation and advice of S. K. Fisk are gratefully acknowledged. This note benefited from critical readings by M. J. Homzie and D. G. Mook.

Inhibition of *Leishmania donovani* transformation by hamster spleen homogenates and active human lymphocytes

HAEMOFLAGELLATES are protozoan parasites responsible for many important diseases of man and domestic animals[1]. *Leishmania donovani*, the cause of visceral leishmaniasis or kala azar, is a widespread human parasitic haemoflagellate. Its life cycle involves man (and other mammals) and an insect vector (sandflies) with a different stage in each of the two host types. Transformation from one stage to the next includes morphological antigenic, physiological, and infectivity changes[2–5].

Transformation in these organisms is a fundamental developmental transition whose regulation is incompletely understood. In this report we present evidence that transformation from the mammalian (amastigote) stage of *L donovani* to the insect and/or culture (promastigote) stage is inhibited by host hamster spleen homogenates and by a soluble factor(s) synthesised by activated human lymphocytes In the absence of this factor transformation proceeds in an orderly series of steps (Fig. 1).

Synchrony of transformation by a population of amastigotes is rather poor; transformation to the promastigotes begins after 18 h with all cells capable of developmental transition (~ 60–80% of the cells undergo transformation) completing cytodifferentiation by about 60 h (Fig. 2). Transforming amastigotes do not incorporate ^{14}C-thymidine[6] into DNA; however, promastigotes readily incorporate this substrate into DNA (~ 70% of recoverable ^{14}C from labelled thymidine is found in DNA). This suggested that *de novo* DNA synthesis does not occur in transforming amastigotes.

We then incubated freshly isolated amastigotes in glucose-free Locke's solution (*p*H 7.7) for 8 h at 27 °C before transfer to transformation medium (HO–MEM)[7] to deplete possible contaminant compounds carried over during isolation that might inhibit cytodifferentiation. The cells transformed more synchronously and the times required for initiation and completion of transformation were markedly reduced (Fig. 2). Even shorter initiation and completion times for developmental transition of amastigote populations were found when cells were preincubated in glucose-free Locke's solution for 8 h at 34 °C before transfer to HO–MEM (Fig. 2).

To determine if a host factor(s) carried as a contaminant with amastigotes during their isolation delayed transformation, 2.5 ml of the first wash from infected spleen homogenates (see legend to Fig. 1) was added to 2.5 ml of

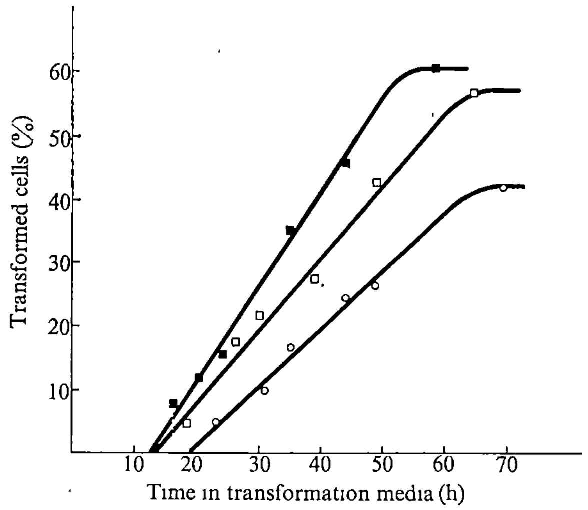

Fig. 2 Transformation of *L. donovani* amastigotes to promastigotes: influence of preincubation in glucose-free Locke's solution on the times of initiation and completion of transformation by a population of washed amastigotes. ○, Control amastigotes transferred to transforming medium (incubated at 27 °C) immediately after isolation from hamster spleen; □, amastigotes preincubated for 8 h at 27 °C before transfer to transformation medium; ■, amastigotes preincubated for 8 h at 34 °C before transfer to incubation medium. Amastigotes (~ 10^8 cells) were incubated in 25-ml Erlenmeyer flasks containing 5 ml HO-MEM (containing glucose). Samples were removed from flasks at various times and the percentage of transformed cells (stage *d* in Fig. 1) determined by microscopic observation. In all experiments the final samples were tested for bacterial contamination; the data from contaminated flasks were discarded.

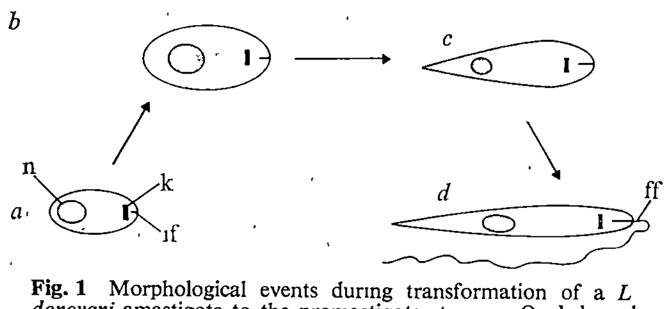

Fig. 1 Morphological events during transformation of a *L donovani* amastigote to the promastigote stage. *a*, Oval-shaped amastigote with nucleus (n), kinetoplast (k) and internal flagellum (if), 0–8 h; *b*, tenfold enlargement of the oval stage, ~ 8–16 h; *c*, elongation of the enlarged parasite, ~ 16–18 h; *d*, formation of free flagellum (ff) and further elongation to complete cytodifferentiation, ~ 18–20 h. Amastigotes were obtained as follows: male hamsters were killed with ether about 2 months after intraperitoneal inoculation with freshly isolated amastigotes (Malakal area Sudan strain, 1S) and the spleen excised in sterile conditions. The spleen was homogenised in 10 ml Tris (0.2 M)–sucrose (0.25 M) buffer, *p*H 7.8, with a Ten Broeck glass homogeniser. Homogenates were centrifuged at 150*g* for 10 min and the pellet discarded; the supernatant was centrifuged at 1,000*g* for 20 min and the resultant supernatant (first wash) discarded. The pellet was resuspended in 10 ml Tris–sucrose buffer and this procedure repeated two more times. After resuspending the final pellet (washed amastigotes) in a small amount of Tris–sucrose buffer, amastigotes were counted and 10^8 cell aliquots incubated in HO–MEM[7] medium at 27 °C. Isolation procedures were carried out in the cold to retard spontaneous transformation, and sterile techniques were used to prevent bacterial contamination. The cell depicted was preincubated in glucose-free Locke's solution (see Fig. 2). About 10% of the preincubated cells started to transform after 8 h in transforming medium. Although stage *a* lasts longer for non-preincubated cells, the duration of time spent in the other stages is the same as that for preincubated cells.

Table 1 Secretion of factors inhibiting *L. donovani* amastigote to promastigote transformation by cell culture systems*

*10^8 washed amastigotes in each flask, incubation temperature 27 °C, transformation determined as in Fig. 2.

†Control amastigotes incubated in absence of cells in same media used to grow tissue cells: RPMI 1640 (GIBCO) or Hanks' MEM (GIBCO).

‡—, No effect on transformation.

§Culture medium RPMI 1640.

¶Culture medium MEM.

Number of experiments in parentheses.

‖Amastigotes inhibited for 3 d or more were washed and transferred to fresh media lacking culture cells to ensure that they were viable and still capable of transformation.

2×HO–MEM before incubation with washed Locke's solution preincubated amastigotes. Addition of the first wash delayed initial transformation times by 12–24 h (four experiments) compared with control cells incubated in 2.5 ml Tris–sucrose buffer and 2.5 ml 2×HO–MEM. Similar results were found when the first wash from uninfected spleen homogenates was tested. Supernatants obtained after the first wash had no effect on amastigote transformation.

Analysis of hamster spleen transformation-blocking activity is difficult because the spleen is small (1–3 g in infected hamsters) and the concentration of the factor(s) responsible for inhibition is low; 1 : 1 dilution of the first wash before adding it to test media resulted in total loss of activity. We decided to find a model system capable of 'mimicking' hamster spleen tranformation-blocking activity and which produced sufficient amounts of factor(s) to analyse inhibition of transformation. Since many developmental processes are mediated by mammalian growth and activating factors (for example, nerve growth factor, epithelial growth factor and lymphocyte-activating factor)[8,9], we therefore tested a number of cell culture systems for their ability to secrete high concentrations of factors capable of inhibiting *L. donovani* amastigote cytodifferentiation.

Conditioned media from four mammalian cell culture lines were able to delay initiation of transformation for at least 12 h· mouse lymphocyte sarcoma cell line 815, phytohaemagglutinin-activated primary human lymphocytes[10], unactivated primary human lymphocytes and mdck, a dog kidney cell line infected by an unidentified mycoplasma (Table 1). Activated primary human lymphocytes and mdck both produced high levels of blocking factors. Further experiments were carried out with only the activated lymphocyte system because it was more active and was better defined than mdck in that it was not infected by mycoplasma. Collection of a large volume of media conditioned by the lymphocytes is relatively simple[10]; this is another advantage with the lymphocyte system.

Incubation of washed amastigotes in medium conditioned by activated lymphocytes delayed the start of developmental transition by 24–48 h (Table 1). Amastigotes incubated with lymphocyte cultures were inhibited from transforming for at least 5 d. When these amastigotes were washed and transferred to fresh media free of lymphocytes cytodifferentiation proceeded normally.

Conditioned medium from activated lymphocyte cultures was separated by ultrafiltration into fractions containing molecules of decreasing molecular weight; these fractions were assayed for transformation-inhibiting activity (Table 2). Activity was localised in fraction IIIc (molecular weight <500); addition of fraction IIIc to amastigotes in HO–

Fraction IIIb (<1,000)	Delayed ≈48 h (3)
Fraction IIIb′ (500–1,000)	—
Fraction IIIc (<500)	Delayed ≈48 h (3)

*Details of primary human lymphocyte preparation, cell culture and collection of conditioned media have been published[10]. Lymphocytes were cultured in MEM supplemented with essential amino acids, glutamine, sodium pyruvate and with 10% foetal calf serum. Cells were activated by addition of 20 μg ml^{-1} phytohaemagglutinin (PHA-P, Difco) and incubated for 5–7 d. Cultures were centrifuged at 300*g* for 5 min to pellet the lymphocytes, and the supernatant saved. Supernatant could be stored frozen or separated into different fractions and then stored frozen.

†Supernatants separated by ultrafiltration into fractions with solutes of different approximate molecular weight. Filtration with an Amicon PM30 resulted in a concentrated fraction of molecular weight >30,000 (fraction I) and a filtrate containing solutes of molecular weight <30,000. The filtrate was further concentrated with an Amicon PM10; the concentrate contained solutes of about 5,000–30,000 molecular weight (fraction II). The material passing through with solutes of molecular weight <5,000 (fraction III) was concentrated using an Amicon UM2; this concentrate is defined as fraction IIIa (solutes of about 1,000–5,000 molecular weight). The material going through the UM2 is defined as fraction IIIb (solutes of molecular weight <1,000). Fraction IIIb was concentrated with an Amicon UM05; the concentrate is defined as fraction IIIb′ (solutes of molecular weight 500–1,000) and filtrate is fraction IIIc (<500 molecular weight).

‡Amastigotes (10^8 cells) incubated in 5.0 ml HO–MEM containing test fraction; concentrated HO–MEM was added to concentrated test fraction in the proper proportions for a final concentration of 1× HO–MEM and 1× test fraction. Transformation was determined as in Fig. 2. Cells were not permanently affected by inhibitory fractions; after delay of transformation the number of amastigotes completing cytodifferentiation was similar to that of controls. Control amastigotes were incubated in 5.0 ml HO–MEM. In all experiments the final samples were tested for bacterial contamination and the data from contaminated flasks discarded.

§Number of experiments in parentheses.

MEM delayed initiation of cytodifferentiation by ~ 48 h. The solutes in fraction IIIc are present in fractions III (molecular weight <5,000) and IIIb (molecular weight <1,000); as would be expected, the latter two fractions show transformation-blocking activity. The lower activity found in fractions IIIb and IIIc may be due to inefficient passage of filtrate through the Amicon UM2 filter membrane. This fraction is relatively stable; it is not inactivated by boiling for 30 min and can be stored at 4 °C for 5 d or at −17 °C for at least several months with little loss of activity.

Transforming amastigote populations can be blocked at any time before the process is complete. Addition of fraction IIIc to amastigotes after 9 h incubation in HO–MEM delayed initiation of cytodifferentiation by about 9 h. Addition of the fraction after 27 h incubation, a time when a few of the cells have already transformed, delayed further transformation for about 15 h. These are unusual results because in most developmental systems there is a point when cells are irreversibly committed to change independent of the initial factor(s) causing that change.

Addition of fraction IIIc or of the first wash from hamster spleen homogenates had no effect on promastigote cultures in HO–MEM. The cells maintained their normal morphology and continued to divide.

The above results present the first evidence for the presence of mammalian regulatory compounds affecting haemoflagellate transformation. There are factors produced by activated human lymphocytes and in hamster spleen homogenates that inhibit transformation of *L. donovani* amastigotes to the promastigote stage. The *in vitro* studies by Lamy[11] with macrophage and Sticker sarcoma cell cultures demonstrating that *L. donovani* amastigotes may occasionally transform into promastigotes while still inside the host cells, can be explained by the possible absence of 'blocking' factors in his cultures.

It remains to be confirmed whether one or more inhibitory factors is present in the lymphocyte secretions and to determine if blocking factors from hamster spleen and cell lines 815 and mdck are similar to those produced by lymphocytes.

Generation of cytotoxic lymphocytes *in vitro* against autologous human leukaemia cells

NORMAL lymphocytes cultured with allogeneic cells in one-way mixed leukocyte culture (MLC) respond proliferatively to the "lymphocyte-defined" (LD) antigens and subsequently cytotoxic cells are generated against the target antigens on the stimulating cells[1]. In contrast, when responding lymphocytes are cultured with stimulating lymphocytes that differ with respect to target antigens but not LD antigens, proliferative and cytotoxic responses are not easily generated; the addition of a second stimulating cell differing from the responding cell with respect to LD antigens in a 'three-cell' experiment allows the generation of cytotoxic lymphocytes directed against target antigens[1–4]. Consistent with results of others[5–9], we have detected low but significant MLC responses after culturing remission lymphocytes with irradiated autologous leukaemia cells; however, cytotoxic lymphocytes were not generated. Using the 'three-cell' approach, where remission lymphocytes, irradiated leukaemia cells and irradiated allogeneic stimulating cells were cocultured, we have generated lymphocytes specifically cytotoxic for autologous human leukaemia cells.

Peripheral blood was obtained at the time of diagnosis from C.T., a 40-yr-old woman with acute myelomonocytic leukaemia (AMML). The peripheral white blood cell count at this time was 200,000 per mm^3, consisting of 52% blast cells. The blood was diluted with medium 199 and layered on a Ficoll–Hypaque gradient[10]; the resulting cells at the interface consisted of 74% blast cells. These cells were washed and control-frozen in RPMI 1640 with 25 mM HEPES buffer and 20% heat-inactivated normal human serum and stored in liquid nitrogen. Eight and twelve weeks after diagnosis, after several courses of intensive chemotherapy, peripheral blood and bone marrow aspirates were obtained. At these times, no leukaemic cells were present in the peripheral blood. Lymphocytes were separated from peripheral blood by Ficoll–Hypaque sedimentation and suspended in culture medium consisting of RPMI 1640 with 25 mM HEPES buffer and 20% heat-inactivated normal human serum. Specimens of bone marrow aspirate obtained at these times were purified in the same way. Approximately 5% of the marrow cells collected from the interface of the gradient were blast cells.

Cultures were set up in 50-ml Falcon flasks, each containing 5×10^6 responding lymphocytes (either the patient's remission lymphocytes or lymphocytes from normal individuals) and $5–10 \times 10^6$ stimulating cells rendered incapable of DNA synthesis by exposure to 2,500 R X irradiation. Stimulating cells were either irradiated leukaemia cells, allogeneic lymphocytes, a mixture of leukaemia cells and allogeneic lymphocytes or a mixture of bone marrow cells and allogeneic lymphocytes. Cultures were incubated at 30 °C in a humidified 5% CO_2 incubator and were fed with 5 ml of culture medium on days 2 and 5. Target cells, to be used on day 7 in the cell-mediated ^{51}Cr release assay (CML) were prepared by culturing either $5–15 \times 10^6$ normal lymphocytes or bone marrow cells in flasks that were fed on days 2 and 5. The leukaemic cells were thawed on the day of the CML assay, incubated for 2 h at 37 °C before labelling with 250 µCi ^{51}Cr ($Na_2\,^{51}CrO_4$,New England Nuclear). Effector cells generated in flasks were collected on day 7 and the CML assay was performed as described in the legend of Table 1*a* and *b*.

In our first experiment shown in Table 1*a*, C.T. remission lymphocytes cultured with autologous leukaemia (L_x) cells alone were not cytotoxic for that patient's leukaemia cells—less ^{51}Cr was released in the presence of CL_x effector cells than was released spontaneously. In contrast, lymphocytes that had been cultured with a mixture of autologous leukaemia cells (L_x) and allogeneic lymphocytes (A_x) were cytotoxic for the patient's

Table 1 *In vitro* generation of lymphocytes specifically cytotoxic for autologous AMML cells

	Responding lymphocytes	Stimulating cells	Effector–target-cell ratio	% Specific ^{51}Cr release ±s.d.			
				Leukaemic cells	Remission marrow cells	Normal lymphocytes from A	Normal lymphocytes from B
(*a*)	C (patient's lymphocytes)	L_x (patient's leukaemia cells) + A_x (normal allogeneic lymphocytes)	40:1	17.8±6.5	3.5±1.4	44.0±4.1	1.8±2.3
	C	L_x	40:1	0.0	0.0		
	C	A_x	40:1	2.9±1.1	0.45±1.6	60.7±10.1	2.2±2.2
	B (normal individual)	L_x	20:1	17.5±12.0	14.7±2.0	−0.7±3.4	−0.4±2.8
	B	A_x	20:1			27.7±2.3	−0.2±3.4
(*b*)				Leukaemic cells	Normal lymphocytes from D	Normal lymphocytes from E	
	C (patient's lymphocytes)	L_x (patient's leukaemia cells) + D_x (normal allogeneic lymphocytes)	20:1	25.0±6.9	30.3±1.7	7.2±3.6	
	C	M_x (remission marrow) + D_x	20:1	22.0±8.9	39.7±3.5		
	C	C_x (patient's remission lymphocytes)	20:1	0.0	0.0	0.0	
	D (normal individual)	L_x	20:1	36.8±6.5	−2.4±4.1		

In both experiments *a* and *b*, lymphocytes were collected 7 d after stimulation, resuspended at 1×10^6–2×10^6 cells ml^{-1} and 0.2 ml effector cells were mixed with 1×10^4 ^{51}Cr-labelled target cells in wells of round-bottom Linbro plates. Supernatants were collected after 6 h (Exp. *a*) or 8 h (Exp. *b*) incubation at 37 °C and % specific ^{51}Cr release was calculated according to the following formula: $[(E-SR)/(M-SR)]\times100$, where E is experimental release, SR is spontaneous release of ^{51}Cr from normal target cells in the presence of medium alone, and M is maximal release of ^{51}Cr from target cells after adding detergent (0.4% Cetrimide). Specific ^{51}Cr release from leukaemic cells and bone marrow cells was calculated from the following formula: $[(E-C)/(M-C)]\times100$, where E is experimental release, C is release of ^{51}Cr from target cells by CL_x or CC_x effector cells and M is maximal release.

leukaemia cells: 17.8% specific ^{51}Cr released observed by 6 h. These same effector cells that were cytotoxic for autologous leukaemia cells and A target cells did not lyse unrelated normal lymphocytes from B and caused only 3.5% ^{51}Cr release from autologous bone marrow cells containing 5% blast cells. It should be noted, however, that these remission bone marrow cells and leukaemia cells were nearly equally sensitive to lysis by allogeneic normal lymphocytes (B) that had been cultured with the patient's leukaemic (L_x) cells Remission lymphocytes that had been cultured with allogeneic (A_x) cells were highly cytotoxic for A target cells (60.7% specific ^{51}Cr release) but caused only 2.9% ^{51}Cr release from autologous labelled leukaemic cells. This indicates that lysis of autologous leukaemia cells by remission lymphocytes that had been cultured with a mixture of A_xL_x stimulating cells was not due to cross reacting target antigens expressed on leukaemia cells and allogeneic (A) lymphocytes. Furthermore, the presence of leukaemic stimulating cells in the mixed culture was necessary for the generation of an anti-leukaemic cytotoxic response.

Remission lymphocytes were obtained 1 month later and it was again possible to generate cytotoxic lymphocytes directed against autologous leukaemia cells (Table 1*b*). Remission lymphocytes cultured with leukaemic cells and allogeneic (D_x) cells caused 25% ^{51}Cr release from leukaemic cells after an 8-h CML assay at the ratio of 20 effector cells per target cell and 30% ^{51}Cr release from allogeneic D target cells. Nearly the same amount of ^{51}Cr (22%) was released from leukaemic cells by lymphocytes that were cultured with bone marrow and allogeneic cells. A probable explanation for this finding is that the number of blast cells carrying target antigens in the stimulating marrow population was sufficient to induce a cytotoxic lymphocyte response. In the experiment shown in Table 1*a*, however, lymphocytes that had been cultured with leukaemic and allogeneic cells caused only 3.5% ^{51}Cr release from labelled marrow cells, for only a minor proportion (5%) of the ^{51}Cr-labelled target cells were blasts, many of which may not have been leukaemic.

The results presented here demonstrate the presence of target antigens on AMML cells against which a cytotoxic autologous lymphocyte response was generated when a strong proliferation-inducing signal (in this case, allogeneic stimulating cells) was provided that presumably stimulates the proliferating helper T cells[1]. The relationship between the target antigens we have detected on AMML cells by cell-mediated cytotoxicity and antigens detected serologically on AMML cells[11] is unknown. We have not had access to cells of other patients with AMML; however, consistent with the results we have reported here, we found that in a patient with acute lymphocytic leukaemia, the development of cytotoxic response aimed at the patient's leukaemia cells was again dependent on the providing of a helper stimulus in a three-cell protocol. Similar experiments with five patients in remission from acute myelogenous leukaemia (AML) have not as yet resulted in generation of cytotoxic lymphocytes directed against autologous leukaemic cells. In some of these cases, the AML cells did not generate cytotoxic activity even in allogeneic responder lymphocytes. The explanation for the lack of finding of cytotoxicity in cases where allogeneic lymphocytes did respond cytotoxically to target antigens on leukaemic cells is not clear.

Consistent with our studies are the independently derived findings of Sondel *et al.* (personal communication) showing that adding a helper stimulus enhances anti-leukaemia cell-mediated cytotoxicity by lymphocytes from siblings HLA identical with the leukaemia patient. The 'three-cell' type approach used in these experiments may thus provide a means for generating cytotoxic lymphocytes directed against other autologous or HLA identical leukaemia or tumour cells that express target antigens but cannot induce a strong lymphocyte proliferative response.

Sensitivity of H–2-less target cells and role of H–2 in T-cell-mediated cytolysis

THERE is no definitive teleological interpretation of the involvement of H–2 determinants in the recognition by mouse cytolytic T cells of various non-H–2 antigens[1,2]. While it is generally believed that T-cell immunity against non-H–2 structures (determined, for example, by infectious agents) may benefit from the known special reactivity of T cells against non-self H–2, other interpretations have been proposed, such as the possibility that H–2 is necessary for cytolysis at a postrecognition stage as the "weak point" of the target-cell surface[3]. A prediction of this hypothesis is that target cells devoid of H–2 should be resistant to T-cell-mediated cytolysis. We have tested this prediction using male germinal cells, embryonal carcinoma and virus-transformed testicular cells as targets, in the presence of the lectin concanavalin A (con A). Con A binding apparently by-passes[4] the normal recognition system, so that lack of recognition of H–2 on H–2-less target cells would not be a limiting factor for cytolysis. We found that H–2-less embryonal carcinoma cell lines, including one with barely detectable levels of F9 antigen, were sensitive to lysis, strongly suggesting that at a postrecognition stage H–2 is not required for T-cell-mediated cytolysis.

Mouse male germinal cells, in practice testicular cells, acquire serologically detectable surface H–2 as late as 12 d of age[5,6]. We wondered whether acquisition of H–2 would be accompanied by a change from resistance to sensitivity to lysis. We found, however, that even testicular cells from several-month-old mice were relatively resistant to lysis, in the presence or absence of con A (Table 1). Further findings (not shown) were: first, ^{51}Cr could be released from testicular cells in the presence of rabbit anti-mouse serum and complement; second, con A induced agglutination of testicular cells at the concentration used in these experiments; third, various ratios of cytolytic to testicular cells and various concentrations of con A did not yield different results. These experiments showed at least that the presence of serologically detectable H–2 was not sufficient to ensure sensitivity to lysis, thus underlining the existence of other, unknown target cell requirements for lysis.

To investigate whether H–2 was necessary for lysis, we then used as targets F9 embryonal carcinoma cells of H–2*b* genotype but devoid of serologically detectable membrane H–2 (ref. 7). Table 2, experiments 1–3, shows, first, that F9 cells were not lysed by anti-*b* cytolytic cells in the absence of con A, and second, that a significant degree of lysis occurred in the presence of con A. This dual pattern was observed in each of eight experiments, not only with *d* anti-*b* and *b* anti-*d*, but also with *k* anti-*b* and *b* anti-*k* cytolytic cells (not shown). Lysis in the presence of con A showed that F9 cells are sensitive to lysis (which incidentally strengthens the conclusions drawn from interesting negative results obtained with TNP-coated F9 cells[8]). That no lysis should occur in the absence of con A therefore strongly suggests that specific anti-H–2 cytolytic cells do not recognise H–2 determinants at the surface of F9 cells. Thus, F9 cells are sensitive to lysis in the presence of con A, in spite of the absence of any H–2 determinant detectable either by specific antisera[7] or by specific cytolytic cells.

Table 1 Lack of demonstrable T-cell-mediated cytolysis of mouse testicular cells

C3H anti-BALB/c (*k* anti-*d*) and BALB/c anti-C3H (*d* anti-*k*) sensitised cytolytic cells were prepared and tested in a ^{51}Cr-release assay as described previously[18], at an effector–target cell ratio of 20:1 in these experiments. Cytotoxicity is expressed as percentage ^{51}Cr release averaged from triplicate wells, minus spontaneous release by target cells alone. In this type of assay, an experimental difference of 5% or more is statistically significant ($P = 0.05$).

*Target cells (prelabelled with ^{51}Cr, 10^4 per V-shaped well of microplates) were P815 mastocytoma cells (H–2*d*), either CBA and C3H (H–2*k*) or BALB/c (H–2*d*) mechanically dispersed testicular cells from mice aged 3 weeks to 7 months, and con A-induced blasts (obtained through 2–4-d incubation of normal spleen cells in the presence of con A (2.5 μg ml^{-1}) then labelled with ^{51}Cr and incubated for two consecutive periods of 15 min with 0.1 M α-methylmannose). Spontaneous release was 9–15 for P815, 20–41 for testicular cells and 14–35 for con A blasts.

†Con A at a final concentration of 10 μg ml^{-1} consistently induced in the presence of sensitised cells nonspecific cytolysis of most target cells tested except testicular cells. It sometimes induced a decrease of specific cytolysis, especially marked here in experiment 5.

F9 cells, however, bear the F9 embryonic antigen[9] and in view of the claimed homology[10] between H–2 and F9 one can argue that the F9 antigen can serve as a substitute for H–2 in lysis. This led us to use strain PCC3/A/1/D-G1, derived from the primitive embryonal carcinoma cell line PCC3/A/1 (ref. 11). PCC3/A/1/D-G1 cells bear neither H–2 nor F9 antigens detectable with antisera and complement and have at least 100 times less F9 antigen than F9 cells in adsorption experiments and only about 1–2% positive cells in an anti-F9 antigen immunofluorescence assay[11]. Table 2, experiments 4–6, and Table 3 show that cytolysis of PCC3/A/1/D-G1 cells followed a pattern similar to that of F9 cells.

Con A-dependent lysis of H–2-less target cells was T-cell-mediated, since it was significantly decreased by anti-Thy 1 serum in the presence of complement, in a specific brain-adsorbable manner (Table 3). Using H–2-bearing target cells, it was found, first, that con A-dependent nonspecific lysis is probably mediated by T cells also capable of mediating specific lysis[4,12–14], and second, that the same drugs inhibit with similar dose–response curves the lethal hit stage of specific cytolysis[15] and con A-dependent nonspecific lysis (P.G., unpublished results). It therefore seems reasonable to assume that both types of T-cell-mediated lysis differ only at the recognition stage and

*Target cells were: EL_4 (C57Bl/6 lymphoma) and P815–X2 (DBA/2 mastocytoma) cultivated *in vitro* in standard conditions; F9 (strain 129 embryonal carcinoma) grown in 15% foetal calf serum in gelatinised flasks, used for experiments within 2 months of subculture; PCC3/A/1/D–G1 (derived *in vitro* from mouse strain 129 embryonal carcinoma cell line PCC3/A/1) grown in 15% foetal calf serum, also used within 2 months of subculture; TSV (SV40-transformed mouse strain 129 testicular cells). Spontaneous release was 11–20, 8–10, 15–31 and 13–30, respectively. The embryonal carcinoma cells were especially sensitive to careless handling.

†Serotypes after refs 7, 9, 11 and unpublished results.

‡Cytolytic cells were C57Bl/6 anti-BALB/c (*b* anti-*d*) and BALB/c anti-C57Bl/6 (*d* anti-*b*). The latter were usually superior to the former in terms of number of cells recovered after sensitisation, percentage of blasts and efficiency of lysis of all types of target cells in the presence of con A.

§Ratio of cytolytic to target cells.

follow the same mechanism after recognition. If this assumption is not correct, then our conclusions below about the sensitivity of H–2-less target cells would still be valid for some cytolytic T cells, but not necessarily for the specifically cytolytic ones.

In this series of experiments, we also tested as targets TSV cells derived from SV40-transformed mouse testicular cells and expressing both H–2*b* and F9 antigen (F.K., unpublished). These cells were lysed to a moderate but significant extent by specific anti-*b* cells with and without con A and by anti-*d* cells in the presence of con A (Table 2). The availability as T-cell-sensitive targets of $H\text{–}2^+$ $F9^+$ virus-transformed and of $H\text{–}2^-$ $F9^+$ carcinoma cells seems of great potential interest. A study of the induction and expression of anti-F9 antigen autoimmunity as a function of the presence of H–2 may help eventually to reveal not only a genetic[16] and ontogenic[10], but also an immunological relationship between H–2 and F9. It is clear from the results reported here that the presence of F9 determinants does not prevent recognition by T cells of H–2 determinants at the target cell surface.

The nature of the primary target cell lesion caused by cytolytic T cells is unknown. Molecular channels can be inserted into the target cell membrane, as in the "doughnut" model proposed by Mayer for complement-mediated lysis[17]. It may also be that 'target molecules' on the target cell membrane have a role, for example as substrates for effector cell membrane enzymes. If this is so, this report shows that neither H–2 nor very probably F9 are the exclusive target molecules, or are exclusively associated with target molecules, since lysis can proceed in their apparent absence. This strongly suggests there is no strict requirement for H–2 at a postrecognition stage, which would account for the H–2 restriction of T-cell-mediated cytolysis.

We thank Mrs L. Andrean for technical assistance, Dr P. Lake for anti-Thy 1 antiserum and the MRC, INSERM, CNRS and Délégation Générale á la Recherche Scientifique et Technique for support.

*Target cells were EL_4 lymphoma and PCC3/A/1/D–G1 embryonal carcinoma cells. Spontaneous release was 13 and 30, respectively. Cytolysis was tested in the presence or absence of con A, at a ratio of 20 effector cells (adjusted before treatment with antiserum) to one target cell.

†Cytolytic cells were either AKR (*k*, Thy 1–1) or C3H (*k*, Thy 1–2) sensitised against C57Bl/6 cells (*b*)

‡Thy 1–1 anti-Thy 1–2 (AKR anti-CBA) antiserum was absorbed either on Thy 1–1 or on Thy 1–2 brain cells. Samples of 0.2 ml were then added to 0 1 ml of medium containing 2×10^6 cytolytic cells, for 30 min at 4 °C. After two washes, the cells were resuspended in 0.5 ml of a 1:10 dilution of complement (guinea pig serum adsorbed on mouse spleen cells) and incubated for 30 min at 37 °C. The cells were again washed twice, resuspended in medium and tested for residual cytolytic activity.

Immune destruction of virus-infected cells early in the infectious cycle

TARGET cells acutely infected with herpes simplex virus (HSV) can be destroyed by human blood mononuclear cells (MC) in the presence of IgG antibody to HSV[1–3], a process termed antibody-dependent cellular cytotoxicity (ADCC). The major effector cell which mediates this reaction is a K cell; it possesses surface Fc receptors which permit attachment to IgG antibody-sensitised target cells[4–6], although the way in which the lethal hit is delivered is poorly understood. For an immune cytolytic mechanism to be maximally effective in limiting the spread of virus in a host, it should be able to destroy the infected cell at an early stage in the viral maturation cycle, before infectious viral progeny can be produced. This requirement seems to be of particular importance for viruses such as HSV, which can avoid exposure to the neutralising antibody in extracellular fluid by spreading from cell to cell across intercellular bridges[7,8]. In this report, we demonstrate that the ADCC mechanism can recognise viral surface antigens as early as 2 h after cells are infected with HSV and can produce target cell death by 3 h after infection (PI), well in advance of the first appearance of both viral progeny and the susceptibility of infected cells to lysis by antibody and complement (AbC).

MC and HSV antibody added to HSV-infected target cells 2 h after infection uniformly led to substantial cytotoxicity but did not injure uninfected target cells (Table 1). Target cell damage induced by ADCC was somewhat decreased at each successive sampling period. This diminished cytotoxicity might be explained by the fact that the MC, prepared at the beginning of each experiment, may have lost some of their cytotoxic activity while standing at room temperature before use. In contrast to ADCC, AbC did not cause significant target cell damage until at least 8 h after infection, and cytotoxicity equivalent in magnitude to that of ADCC was not seen until 24 h PI. In separate experiments, we found that the amount of ADCC-mediated damage of cells 2 h after infection was related directly to the input of infectious virus. In a representative experiment, cytotoxicity was 43.9% when a relatively high multiplicity of infection (MOI) (15 PFU per cell) was used, 15.7% at a moderate MOI (1 PFU per cell), and only 2.3% at a low MOI (0.1 PFU per cell).

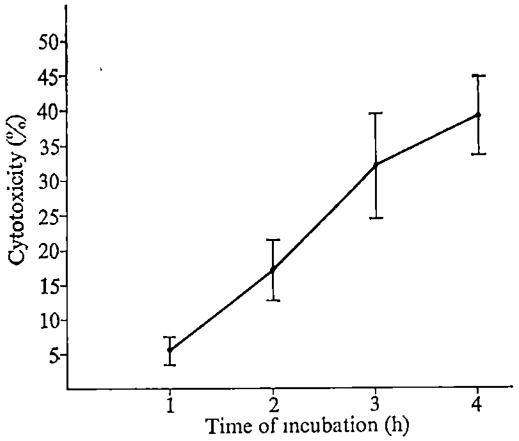

Fig. 1 Kinetics of killing of HSV-infected target cells 2 h PI by antibody-dependent cellular cytotoxicity. The curve represents the mean of four experiments. The vertical bars indicate 1 s.e.m.

Because the ADCC assay uses an incubation period of 4 h, during which the density of viral surface antigen would be expected to increase, the cells used as targets 2 h after infection may have been lysed at any time between 2 and 6 h after infection. To determine when lysis actually began, we measured the release of ^{51}Cr from target cells 2 h after infection at hourly intervals during the standard 4-h incubation period. The results (Fig. 1) indicate that a small but significant cytotoxic effect occurred as early as 1 h after the start of incubation, although most of the cell damage occurred during the ensuing 3 h. These findings indicate that some target cells are lysed as early as 3 h after infection starts.

To determine how early after infection HSV-infected cells could be recognised as foreign by the ADCC process, we

NT, not tested. ^{51}Cr-labelled Chang liver cells (CL) in suspensions were exposed to the VR3 strain of type 1 HSV at a multiplicity of infection (MOI) of 15 plaque forming units (PFU) per cell for 1 h at 37 °C. The CL were then washed and adjusted to 6–10 × 10^5 ml^{-1} in Eagle's minimum essential medium (MEM) with 2% inactivated foetal calf serum (FCS). The cell suspension was incubated at 37 °C in a humid air–5% CO_2 atmosphere. The time of transfer to the incubator was designated zero hour PI. At various times PI, portions of the cell suspension were frozen at −70 °C for determination of infectious virus titres. The remaining cells were chilled in an ice–water bath, washed by centrifugation at 4 °C, and then adjusted to 5 × 10^4 ml^{-1} in MEM with 10% FCS for assessment of their susceptibility to lysis by ADCC and lysis by AbC. ADCC and AbC were assayed as before[3], except that the incubation period (4 h) for ADCC was shorter. The effector cells for ADCC were Ficoll–Hypaque separated MC from the venous blood of normal subjects. The effector cell–target cell ratio was 50:1. Fresh guinea pig serum at a final dilution of 1:10 was the source of complement (C) in the AbC assay. The antibody source was a pool of heat-inactivated human serum from ten HSV seropositive donors; it had a lymphocyte-dependent antibody titre of 30,000 and a complement-dependent cytolytic antibody titre of 800 against type 1 HSV-infected CL[3]. Heat-inactivated pooled serum from six seronegative donors served as a control. The serum pools were used at final dilutions of 1:100 for ADCC and 1:10 for AbC, which have been shown to produce optimal lysis[3]. Cytotoxicity due to ADCC was defined as the percentage ^{51}Cr released from target cells in the presence of MC and antibody-positive serum (PS) minus the percentage ^{51}Cr released from target cells in the presence of MC and antibody-negative serum (NS). PS alone was without effect. Cytotoxicity due to AbC was defined as $[(W-X)-(Y-Z)]$, where the symbols represent the percentage ^{51}Cr release from cells treated with PS and C (W), with PS and heat-inactivated C (X), with NS and C (Y), and with NS and inactivated C (Z). Background release for infected CL was 4–10% during 4 h except for cells 24 h PI, whose release was as high as 20%. Background release for uninfected cells was 10–15%. All values are the means of triplicate determinations. Significant cytotoxicity was defined as calculated values of at least 5% (ref. 3).

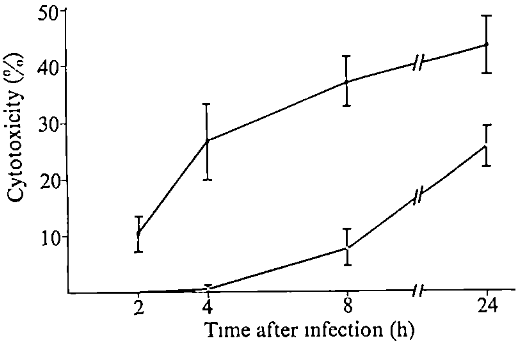

Fig. 2 Recognition of viral antigens on HSV-infected cells at various times after infection by antibody-dependent cellular cytotoxicity (●) and by antibody and complement (○). The curves represent the mean of five experiments in which lysis by ADCC was measured and the mean of three experiments in which lysis by antibody and complement was also measured.

incubated 10^6 CL at various times after infection with 1 ml of a 1:10 dilution of either HSV antibody-positive or HSV antibody-negative serum for 15 min at room temperature. The cells were then chilled in an ice–water bath, and excess unbound antibody was removed by washing them three times at 4 °C with MEM containing 2% foetal calf serum. We confirmed the absence of free lymphocyte-dependent antibody (LDA) by testing the supernates of the final cell washing for LDA activity against HSV-infected CL[2]. Thus, any cytotoxicity shown by these cells after subsequent exposure to MC or complement indicates recognition of viral antigens which were present at the time antibody was added rather than later during the test period. As Fig. 2 shows, ADCC recognised infected cells as antigenically foreign as early as 2 h after infection, whereas AbC, as before, was inactive until 8 h after infection. Presensitisation of target cells followed by removal of free antibody resulted in less ADCC at 2 h after infection than was observed when antibody and MC were added together (as in Table 1). This may be due to two factors. First, when unbound antibody is removed, the free antibody is not available to recognise infected cells that develop a density of viral surface antigen sufficient to support ADCC later than 2 h after infection but before the end of the 4-h test period. Second, the sparseness of viral surface antigens 2 h after infection may not permit firm attachment of antibody to the cell surface so that bound antibody may dissociate during cell washing.

To confirm that the ADCC mechanism recognises and destroys HSV-infected cells before infectious viral progeny appears, we determined the amount of infectious virus in the CL cultures at various times after infection by plaque titration. The results (Table 2) are typical of four experiments and show that infectious viral progeny were not detected until 8–12 h after infection. On the other hand, viral surface antigen, as measured by direct immunofluorescence, was first noted at 4 h after infection and reached a plateau at 8 h after infection (Table 2). Twenty-five to fifty per cent of the infected, but none of the uninfected cells, also showed a very faint, randomly distributed granular fluorescence within several minutes after exposure to HSV. This fluorescence persisted unchanged until at least 2 h after infection. We interpreted this as indicating the presence on the cell surface of virus which had adhered but not penetrated. Using the binding of radioiodinated antibody to detect viral surface antigen, other investigators have made a similar observation with cells exposed to HSV at a relatively high MOI (ref. 9). Perhaps, by coating the cell surface with antigenic material, this adherent non-penetrating virus may contribute to the early killing of infected cells by ADCC. The quantitative contribution of this phenomenon to ADCC activity is probably small, however, since cytotoxicity seems to be directly related to the *de novo* synthesis of viral antigen by the infected cell (Fig. 2) as indicated by the increase in ADCC with increasing time after infection.

Table 2 Infectious virus titre and membrane fluorescence at various times after infection

Times PI (h)	Virus titre (PFU ml^{-1})	Membrane fluorescence (% positive)
0	2.3×10^6	0
2	1.4×10^6	0
4	1.2×10^6	9
6	9.0×10^5	NT
8	1.3×10^6	84
12	6.7×10^6	NT
24	5.0×10^7	95

For determination of total virus at various times PI, cell suspensions (7×10^5 per ml) were frozen and thawed three times, and 0.1-ml samples were plated on to CL monolayers for 1 h at 37 °C. The monolayers were incubated for 5 d at 37 °C in a CO_2 incubator under a semi-solid overlay of 0.7% Agarose before staining with crystal violet and counting of plaques. Surface membrane fluorescence at various times PI was assessed by incubating 3-5×10^5 cells with 0.1 ml of a 1:15 dilution of a fluorescein-conjugated rabbit anti-HSV serum (supplied by A.J. Nahmias, Emory University) for 15 min at 37 °C. The cells were washed three times in ice-cold normal saline. At least 200 cells per preparation were then examined for surface fluorescence under ortho-illumination in a Zeiss fluorescence microscope. Cells with partial or complete rims of fluorescence were counted as positive.

In summary, ADCC can recognise cells infected with type 1 HSV as early as 2 h after infection and produces detectable cell lysis by 3 h after infection. This is well in advance of the appearance of the first mature viral progeny at 8 h PI or later. Consistent with previous studies using HSV-infected cells[10], susceptibility to lysis by antibody and complement is not apparent earlier than 8 h PI. Although we have not directly shown that ADCC inhibits viral replication *in vitro*, our observations suggest that this is a likely consequence of cellular injury at such an early stage in the viral maturation cycle. Because ADCC requires only modest amounts of antibody to operate efficiently[11], it should be particularly important in host defence by helping to limit viral spread during the acute phase of a primary infection when specific viral antibody is just beginning to be produced.

Increased ornithine decarboxylase activity in murine sarcoma virus infected cells

POLYAMINE biosynthesis is one of the earliest events occurring during cellular proliferation[1,2], and the rate at which it proceeds[3] is limited by ornithine decarboxylase (ODC), an enzyme which catalyses the formation of putrescine from ornithine. ODC levels are low, but stable, in resting cells, and a large increase in activity occurs rapidly after the onset of growth[4,5]. Elevated ODC levels occur in certain tumour cells, including hepatoma, neuroblastoma and SV40-

transformed cells[3-7]. Fast growing hepatomas have higher enzyme levels than slow growing ones[6]. During Rous sarcoma virus (RSV) transformation, elevation of ODC levels precedes morphological change[8].

Here we describe the marked elevation of ODC levels which occurs in murine sarcoma virus (MSV)-infected cells. The continuous, contact inhibited, non-tumorigenic cell line BALB/3T3 (ref. 9) was used for these studies because it has a short doubling time and is readily transformed by MSV. Gz-MSV (ref. 10), which consists of a transforming virus and a non-transforming strain of murine leukaemia virus (MuLV), was grown in BALB/3T3 cells. The MuLV acts as a 'helper' virus, enabling the defective MSV to complete its replication cycle. Cells transformed by MSV in the absence of 'helper' virus contain the sarcoma genome, but do not release infectious virus (non-producer cells)[11]. Rauscher leukaemia virus[12] (RLV), a non-transforming strain of MuLV, was obtained from the supernatant fluids of chronically infected BALB/c cells. BALB/3T3 cells, clone A31, and KA31, Kirsten MSV virus-transformed non-producer A31 cells, were obtained from Dr Stuart Aaronson.

Table 1 Properties of cell lines

Cell line	Population doubling time (h)	Colony forming efficiency (%) Liquid medium	Colony forming efficiency (%) Soft Agarose	Virus production (% infectious centres) MSV	Virus production (% infectious centres) MuLV
B/3T3	23	51.5	<0.01	<0.1	<0.1
RLV infected (MOI* 3:1)	23	48.5	<0.01	<0.1	75.0
MSV infected (MOI 1:1)	43	10.5	0.8	46.5	100
KA31	16	48.0	28.0	<0.1	<0.1

Cells were seeded at a density of 5×10^3 cm^{-2} in growth medium (Dulbecco's modification of Eagle's minimal medium, supplemented with 10% foetal bovine serum and antibiotics). Virus infections were performed in suspension (1 h, 37 °C) before seeding. Total and Trypan blue resistant cell counts were performed 1, 3, 4, 5 and 7 d after seeding. Cells were collected 7 d after seeding and tested for colony forming efficiency in liquid (growth) medium and soft Agarose (0.4%). Virus production was measured 7 d after infection by infections centre assays. Indicator cells were seeded (1×10^5 cells per 60-mm dish) 24 h before addition of test cells, and foci of morphologically altered cells enumerated 5 d later[12,13]. BALB/3T3 cells were the indicator for MSV production and the S+H− cell line A1-2 for MuLV production.

*MOI, multiplicity of infection.

The properties of the cell lines used are presented in Table 1. RLV infection of BALB/3T3 cells did not alter the growth rate or colony forming efficiency (CFE) in liquid medium The RLV infected cells remained contact inhibited, and were unable to grow in soft Agarose. KA31 non-producer cells were morphologically transformed, had a short doubling time, and formed colonies when suspended in soft Agarose. MSV infected B/3T3 cells released MSV and MuLV, and were morphologically transformed but their CFE in soft Agarose was low. Their population doubling time was greatly increased and their CFE in liquid medium decreased. Trypan blue uptake studies revealed only a modest increase in the number of non-viable cells (from < 2% in the control cells to up to 8% in the MSV infected cells). The reason for the increased doubling time after acute MSV infection is not understood, but it also occurs in cat cells acutely transformed by the feline leukaemia virus pseudotype of MSV (ref. 14). Apparently many of the cells acutely infected with MSV retain the ability to exclude Trypan blue, but fail to divide, perhaps due to cytogenetic alterations (chromosome breaks and pulverisation) induced by MSV (P. Fischinger, personal communication).

ODC levels of BALB/3T3 cells were growth dependent (Fig. 1). Maximum levels, reached during exponential growth, occurred four days after seeding. The decrease in cell growth that preceded saturation density was accompanied by a rapid drop in ODC activity, and basal levels were reached at saturation density. RLV infection had no effect on ODC levels. Transformed KA31 cells had a maximum ODC level approximately twice that of BALB/3T3 cells. Acute MSV infection, at both high and low multiplicities, resulted in a rise of 6–26-fold in maximum ODC activity. The rise commenced at the onset of morphological transformation, and maximum levels coincided with mass transformation of the culture. ODC activity remained elevated during the remainder of the 7-d observation period. When MSV infected cells were trypsinised and reseeded at seven-day intervals (Fig. 2), maximum ODC levels during subsequent passages were about twice as much as uninfected control cells.

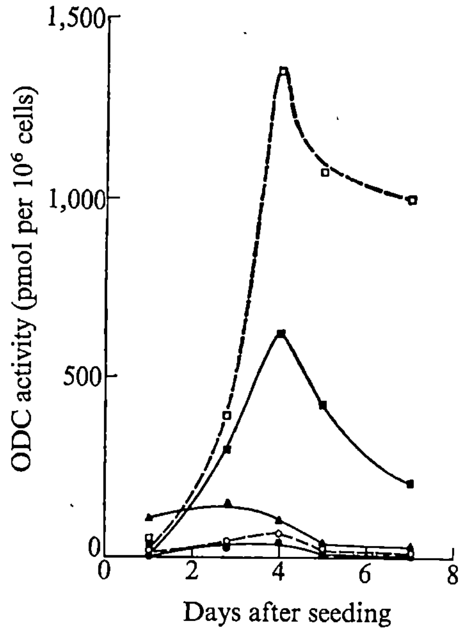

Fig. 1 ODC activities of cell lines. See Table 1. Cell lines were virus infected at the multiplicities (MOI) indicated immediately before seeding. Cells were seeded in 100-mm plastic plates (Falcon) at densities of 5×10^3 cm^{-2}. At 1, 3, 4, 5 and 7 d after seeding, replicate plates of each line were rinsed twice with saline and frozen (−20 °C), until assayed. For ODC assays, cells were gently scraped into 1 ml buffer (50 μM EDTA, 25 μM pyridoxal phosphate, 2.5 mM dithiothreitol in 25 mM Tris-HCl, *p*H 7.1), freeze–thawed three times, and centrifuged (4,500*g* for 10 min). Supernatant fluids (0.25 ml) were incubated with 50 μl 1-^{14}C-ornithine (0.2 μCi, 6.25 nmol) in plastic tubes equipped with a rubber stopper supporting a polyethylene centre well. After incubation (37 °C, 45 min), 0.2 ml hydroxide of hyamine was injected into each centre well. After a further incubation of 15 min, 0.2 ml 6% perchloric acid was added to stop the reaction. Tubes were agitated for 15 min to release bound CO_2, the centre wells were then removed and their radioactivities determined. The experiments were performed five times. Results of a representative experiment are demonstrated. ●, BALB/3T3 control; ○, RLV infected (MOI 3:1); ■, MSV infected (MOI 0.1:1); □, MSV infected (MOI 1:1); ▲, KA 31.

Our data demonstrate that a marked rise in ODC activity occurs in cells acutely infected with MSV. This rise is due to the transforming virus component of the MSV complex, as infection with non-transforming MuLV has no effect. The rise in MSV infected cells is not due to an increased rate of cellular division, since most acutely infected cells fail to divide. Rapidly dividing, chronically transformed cells (both virus producing and non-producing) have maximum ODC levels approximately double that of non-transformed parent cells.

The increased ODC levels of virus transformed and other malignant cells may be related to the higher polyamine content of tumour cells and to the increased excretion of polyamines in the urine of cancer patients[15].

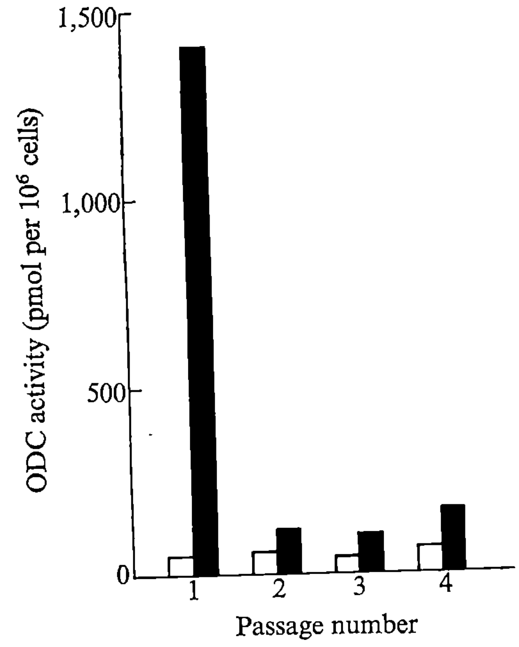

Fig. 2 Maximal ODC levels of MSV BALB/3T3 cells. See Table 1 and Fig 1. Cells were infected at a MOI of 0.1:1 immediately before seeding at a density of 5×10^3 cm^{-2}. Control and infected cells were trypsinised at 7-d intervals and reseeded at the same density. Cells were collected 4 d after seeding for ODC determinations. Open columns, control cells; solid columns, MSV infected cells.

We thank Drs George J. Todaro and John D. Minna for advice and encouragement, and Mrs Theresa Gregorio for technical assistance.

Single ionic channels induced in lipid bilayers by polyene antibiotics amphotericin B and nystatine

AMPHOTERICIN B and nystatine increase the permeability of lipid membranes to ions, water and non-electrolytes[1,2]. Cholesterol (or some other sterols) is a necessary membrane component for the antibiotics to be effective[1,3]. Permeability to water and non-electrolytes increases linearly with ion permeability[2]. The molecules of the size of glucose and larger are essentially impermeant. It is concluded[2,4] that amphotericin B and nystatine form aqueous pores with an effective radius of approximately 4 Å in thin lipid membranes. The changes in membrane conductance connected with the formation of a single pore have, however, not yet been observed. In this paper the properties of individual conductance channels induced in black lipid membranes by amphotericin B and nystatine are described briefly.

Black lipid membranes were formed across a 0.5-mm diameter hole in a 1-ml Teflon cup from *n*-hexane solutions of brain lipids (20 mg ml^{-1}) purified from neutral lipids by acetone extraction. A certain amount of recrystallised cholesterol (usually 1 mg ml^{-1}) was added to the membrane-forming solution. The membrane currents were measured with the Keithley-301 electrometer. The water-soluble sodium salt of amphotericin B or stock solution of nystatine in dimethylsulphoxide (10^{-3} M) were added at equal concentrations to both aqueous solutions buffered with 10 mM potassium phosphate. All the measurements were carried out at *p*H 6.0 and 22–23 °C. The specific conductance of black lipid membranes in the 2 M KCl solution in the absence of antibiotics was about 2×10^{-9} mho cm^{-2}.

When amphotericin B was added at a concentration of $2\text{–}3\times10^{-8}$ M to both electrolyte solutions discrete current jumps can be observed on the membranes formed from the heptane–lipid solution with a phospholipid–cholesterol weight ratio of 20:1 (Fig. 1).

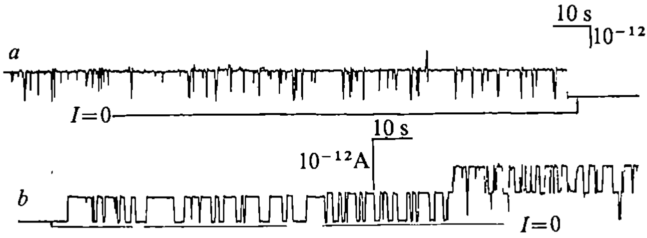

Fig. 1 Fluctuations in membrane current in the presence of 3×10^{-8} M amphotericin B and 2M KCl (*a*), and 1×10^{-7} M amphotericin B and 2 M KNO_3 (*b*). Membrane potential 200 mV. Arrows show current through an unmodified membrane. Phospholipid–cholesterol ratio, 20:1.

The probability of the appearance of these conductance jumps (about 6 pmho in 2 M KCl with a membrane potential of 200 mV) depended markedly on the cholesterol content of the membrane-forming solution. With the cholesterol-depleted lipids the membrane conductance did not increase even if amphotericin B at a concentration of 5×10^{-7} M was added symmetrically to the aqueous solutions. At a phospholipid–cholesterol ratio of 100:1, the current jumps could be observed at 10^{-7} M amphotericin B, whereas at a ratio of 2:1, only a $1\text{–}2\times10^{-9}$ M concentration of the antibiotic was required. The size of the jumps did not depend on the cholesterol concentration. Being added only to one side of the membrane with a 20:1 ratio of phospholipid–cholesterol, amphotericin B did not increase the membrane conductance even at a concentration of 4×10^{-5} M. In all the experiments described below the phospholipid–cholesterol ratio was 20:1.

The stepwise conductance changes observed seem to be the result of the formation of single ionic channels, each having only two states: one open and one closed. After being formed, the channel exhibits many transitions between the two states. All the transitions shown in Fig. 1*a* can be related to the same channel because there are no double or other multiple levels characteristic of simultaneous operation of several independent channels. The distribution functions of dwell times for both the open and closed states of an individual channel are single exponentials. The average dwell time in each state does not depend on the membrane potential.

The dependence of a single-channel conductance on KCl

Table 1 Variation in amphotericin B channel parameters with KCl concentration

	KCl (M)				
	0.5	1.0	1.5	2.5	3.5

τ_o, Average dwell time of a channel in the open state.

τ_c, In the closed state.

concentration (Table 1) shows saturation. The voltage–current characteristic of a single channel and a multichannel membrane are shown in Fig. 2. The channel conductance increased slightly with membrane potential. In asymmetrical conditions (1 and 3 M KCl), the values of the zero current potentials were the same for the single channel (17±2.0 mV) and for the multichannel membranes (18.5±0.5 mV), within the limits of experimental errors. Transport numbers for the channel (T_{Cl} = 0.85 and T_K = 0.15) were similar to those found previously for the multichannel membranes in the experiments with low salt concentration[1]. Thus, non-ideal anionic permeability of a membrane in the presence of amphotericin B is not the result of simultaneous operation of two types of channels—cationic and anionic—but it is an intrinsic property of each individual channel.

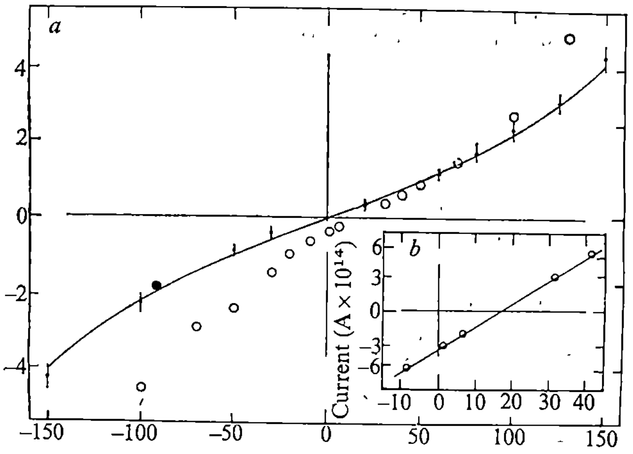

Fig. 2 Current–voltage characteristics of the membrane in the presence of amphotericin B; *a*, points characteristic of a single-channel membrane in a symmetrical solution: 1 M KCl and 6 × 10^{-8} M amphotericin B; curve, characteristic of the membrane with approximately 200 channels, in a symmetrical solution: 1 M KCl and 2 × 10^{-7} M amphotericin B. The current scale for the curve was chosen to fit the point at +100 mV. ○, Characteristic of a single-channel membrane separating solutions of 1 M KCl and 3 M KCl; 3 × 10^{-8} M amphotericin B in both solutions. The sign of the potential is given for the 3 M KCl solution *b*, Region of characteristic of a single-channel membrane in asymmetrical conditions near the point of zero current potential.

The main feature of amphotericin B channels is the dependence of their formation and properties on the type and concentration of salt. Single channels could be observed in solutions of high concentrations of such salts as KCl, KBr, KF, KNO_3, CsCl, CsBr, CsF, $CsNO_3$, $RbNO_3$, $CaCl_2$. As a rule these channels have only two states. The jumps of intermediate values, however, were rarely observed, as can be seen in Fig. 3. Table 1 demonstrates that the amphotericin B concentration necessary to obtain a few channels was influenced by salt concentration. Formation of the channels depended on the type of cation as well as anion. If the membrane was formed in solutions of electrolyte with a large cation (2 M acetylcholine chloride) or a large anion size (2 M potassium propionate), the membrane conductance did not increase even at an amphotericin B concentration of 10^{-6} M. In NaCl solutions single channels were observed only at a rather low salt concentration (up to 2 M). In a solution of 2 M NaCl the channel conductance was about 3 pmho. In solutions of higher NaCl or NH_4Cl concentrations (3–4 M), there are only random changes of conductance with irregular jumps of no more than 0.2 pmho.

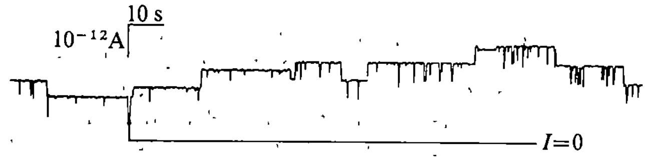

Fig. 3 Current against time record: 5 M CsCl and 2 × 10^{-8}M amphotericin B. Membrane potential 100 mV.

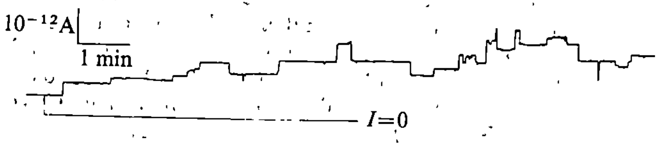

Fig. 4 Current against time record: 3 M KCl and 10^{-7} M nystatine. Membrane potential 200 mV.

One more interesting property of amphotericin B channels is the salt dependence of their gates. Figure 1 shows that the dwell time of the channel in both states at a given voltage were different in KCl and KNO_3 solutions of the same concentration. Moreover the average time which the channel spends in the open state (τ_O) depends on salt concentration, as can be seen in Table 1.

Another polyene antibiotic, nystatine, also induced discrete changes of lipid membrane conductance. In contrast to amphotericin B channels, the presence of smaller jumps and somewhat longer dwell times for the open channels were characteristic of the nystatine channels (Fig. 4).

We thank Dr E. D. Etingov for amphotericin B and nystatine, and Dr A. Ya. Silberstein for discussions.

Release of novel prostaglandins and thromboxanes after immunological challenge of guinea pig lung

THE ability of lung tissue from various species to synthesise and release parent prostaglandins (PGs) has been well established[1,2] and metabolic conversions of PGs occur rapidly after very efficient uptake from the circulation[3,4]. Using an isolated perfusion system to allow uptake of the PG precursor, arachidonic acid

(1-^{14}C labelled), the sensitised guinea pig lungs released a number of radiolabelled substances following challenge with specific antigen[5]. Our attempts to characterise these substances and prepare sufficient material for biological testing have revealed at least two compounds which have not been previously described and others not previously seen in this release system.

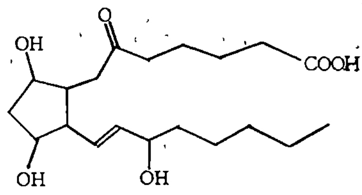
Guinea pigs were sensitised to ovalbumin (100 mg intraperitoneally and subcutaneously) and after 3 weeks were killed and their lungs perfused with Tyrode solution[6]. The sensitised lungs were challenged during perfusion with ovalbumin (5 mg), the perfusate collected for 10 min after challenge and stored at 4 °C under nitrogen. A control group of guinea pigs was also perfused without challenge. The compounds of interest in the perfusate were transferred into organic solvent by adsorbing them on to XAD-2 resin (Rohm and Haas) and eluting with methanol. The concentrated methanol extract was then applied on to a silicic acid column and the various substances removed by stepwise elution with increasing concentration of methanol (0–10%) in chloroform. The eluates were concentrated by vacuum distillation and derivatised for gas liquid chromatography and mass spectrometric analysis (GLC–MS).

The following known PGs and related compounds were identified by GLC–MS following their isolation from sensitised challenged guinea pig lungs; (1) 12-hydroxy-5,8,10-heptadecatrienoic acid (HHT)[7], (2) the hemiacetal of 8-(1-hydroxy-3-oxopropyl)-9,12-dihydroxy-5,10-heptadecadienoic acid (PHD: thromboxane B$_2$)[7,8], (3) PGE$_2$, (4) 15-oxo-PGE$_2$, (5) 15-oxo-13,14-dihydro-PGE$_2$, (6) PGF$_{2\alpha}$, (7) 15-oxo-PGF$_{2\alpha}$, (8) 15-oxo-13,14-dihydro-PGF$_{2\alpha}$. In addition, two new related compounds were characterised, namely 6-oxo-PGF$_{1\alpha}$ (compound 1) and 7-{2, 4-dihydroxy-6-(3-oxo-1-octanyl)-tetrahydropyran-5-yl}-*cis*-5-heptenoic acid (compound 2). No identifiable levels of these compounds were noted in the control extracts.

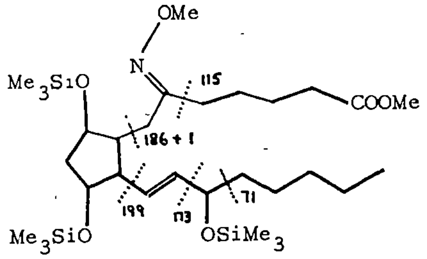
The mass spectrum and the source of the major fragments of compound 1 as its methyl ester, methoxime, trimethylsilyl derivative is shown in Fig. 1. Ions at *m/e* 173 and *m/e* 199 support the presence of a 15-hydroxy group and a 13,14-double bond[9]. The ion at *m/e* 217 is typical of the F-prostaglandin ring system[9]. The ion at *m/e* 187 is formed by a McLafferty rearrangement (not possible for a methoxime substituent at C7) with the hydrogen at C9 and confirms the structure of the α chain. Additional evidence for the location of the oxo group at C6 is provided by the ion at *m/e* 115.

The structures of the ions at *m/e* 115 and *m/e* 187 are supported by the appearance of ions at *m/e* 118 and *m/e* 190 in the spectrum of the corresponding trideuteromethyl ester of compound 1*A*. Significantly, this spectrum lacks ions at *m/e* 104 and 176, thereby excluding location of the oxo group in compound 1 at C5. The corresponding benzyl-oxime of compound 1*A* also exhibits the ion at *m/e* 115 but in this case the McLafferty rearrangement ion appears at *m/e* 263. Finally, the spectrum of compound 1 after methylation, borohydride reduction of the oxo group, followed by silylation, exhibits an intense ion at *m/e* 217. The intensity of this ion reduces by approximately 50% in the corresponding sodium borodeuteride product, and appearance of an ion at *m/e* 218 is noted. This ion at *m/e* 218 is consistent with the incorporation of one deuterium atom at C6 and subsequent cleavage in the derivative at the C7, C6 bond, alpha to the newly incorporated trimethylsilyl group. These facts are all consistent with the structure of compound 1 being 6-oxo-PGF$_{1\alpha}$.

The mass spectrum of compound 2 as its methylester, methoxime, trimethylsilyl derivative, is shown in Fig. 2 with its major fragments. The ion at *m/e* 174 is typical of the aldehydic unit of the thromboxane system[7] (this appears at *m/e* 183 in the spectrum of the *d*-9 trimethylsilyl derivative). The absence of an



1



1*A*

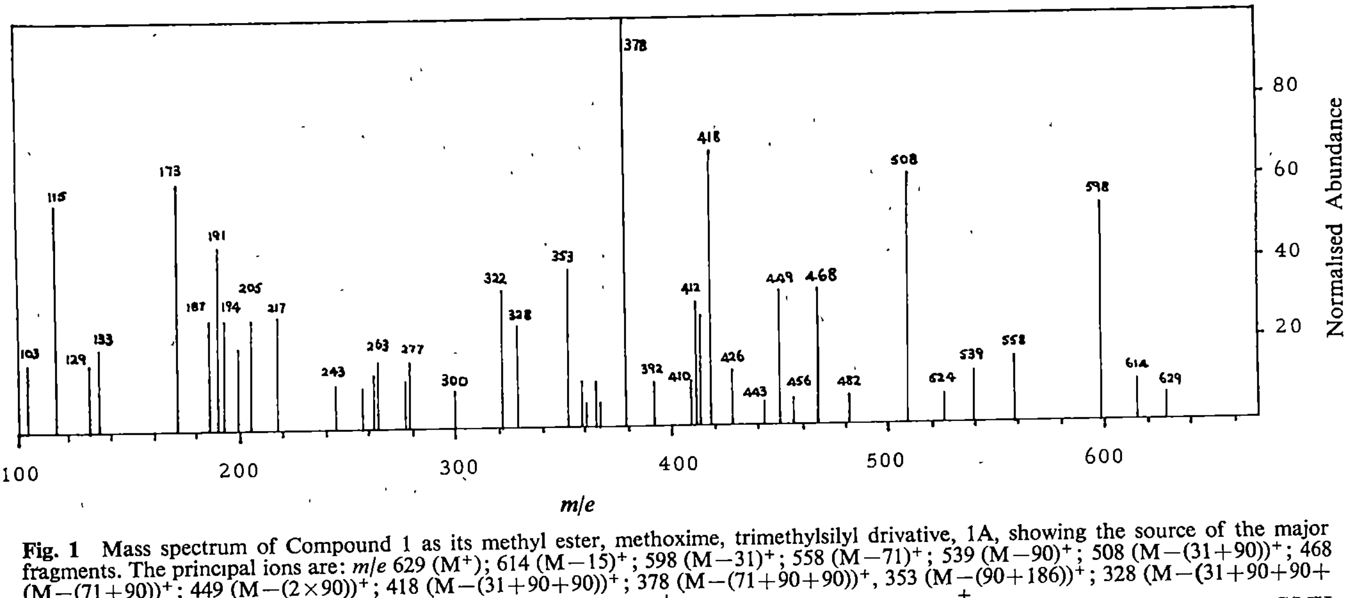


Fig. 1 Mass spectrum of Compound 1 as its methyl ester, methoxime, trimethylsilyl drivative, 1A, showing the source of the major fragments. The principal ions are: *m/e* 629 (M$^+$); 614 (M−15)$^+$; 598 (M−31)$^+$; 558 (M−71)$^+$; 539 (M−90)$^+$; 508 (M−(31+90))$^+$; 468 (M−(71+90))$^+$; 449 (M−(2×90))$^+$; 418 (M−(31+90+90))$^+$; 378 (M−(71+90+90))$^+$, 353 (M−(90+186))$^+$; 328 (M−(31+90+90+90))$^+$; 217 ($Me_3Si\overset{+}{O}=CH-CH-OSiMe_3$); 199 ($CH=CH-CH(\overset{+}{O}SiMe_3)C_5H_{11}$); 191 ($Me_3Si\overset{+}{O}=CH-OSiMe_3$); 187 ($(CH_2=C(NH OMe)(CH_2)_4COOMe)^+$); 173 ($Me_3Si\overset{+}{O}=CHC_5H_{11}$); 115 ($((CH_2)_4COOMe)^+$).

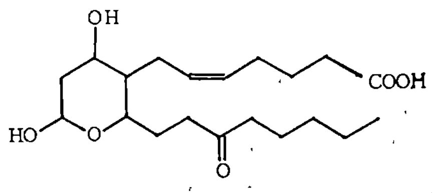
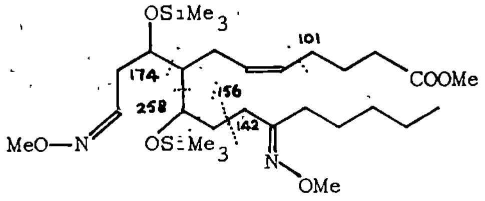


2



2A

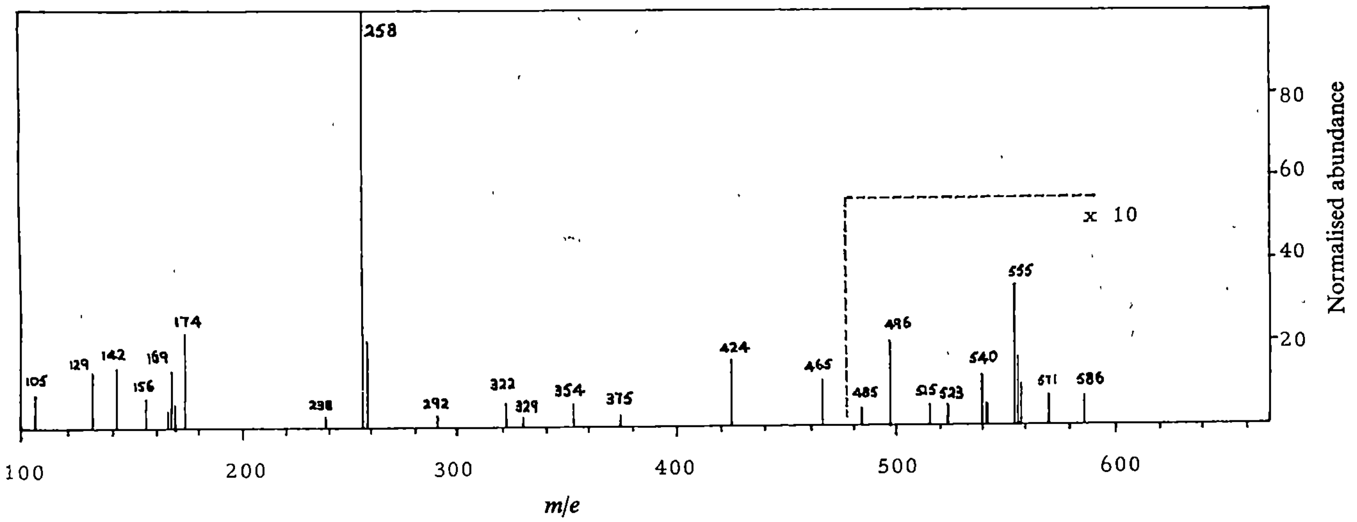


Fig. 2 Mass spectrum of compound 2 as its methyl ester, methoxime, trimethylsilyl derivative 2*A*, showing the source of the major fragments. The principal ions are: *m/e* 586 (M^+); 555 $(M-31)^+$: 496 $(M-90)^+$; 485 $(M-101)^+$; 465 $(M-(31+90))^+$; 424 $(M-(90+72))^+$; 375 $(M-(31+90+90))^+$; 354 $(M-(31+90))^+$; 329 $(M-(101+156))^+$; 322 $(M-(90+174))^+$; 258 $(Me_3Si\overset{+}{O}=CH(CH_2)_2C(=NOMe)C_5H_{11}$, 174 $(HC(=NOMe)CH_2CH=\overset{+}{O}SiMe_3)$; 156 $((CH_2)_2C(=NOMe)C_5H_{11})^+$; 142 $(CH_2C(=NOMe)\ C_5H_{11})^+$; and $(Me_3Si\overset{+}{O}=CH\text{–}CH_2CN)$.

ion at *m/e* 173 suggests modification of the lower chain from that of thromboxane B_2. Losses of 156 and 142 and ions at these masses (all noted for the *d*-9 trimethylsilyl derivative) indicate a saturated β chain containing an oxo substituent. The base peak at *m/e* 258 (267 in the *d*-9 trimethylsilyl derivative) is equivalent to that at *m/e* 301 in the corresponding thromboxane B_2 derivative[7]. The structure of the top chain is supported by the loss of the 101 fragment (104 in the corresponding trideuteromethylester of 2*A*). These facts accord with compound 2 having a structure equivalent to that of an oxo-dihydro derivative of thromboxane B_2.

Table 1 Chromatographic characteristics and relative amounts of compounds isolated after immunological challenge of guinea pig lung

*% MeOH in $CHCl_3$ on silicic acid, each fraction being 20 ml total volume.

†Retention time relative to fatty acid esters on 1.2% SE 30 at 230 °C for methylated, methoximated, silylated compounds. Compound 1 is not resolved into doublet except as benzyl-oxime derivative.

‡Calculation based on 3 groups of pooled perfusates each derived from 200 guinea pigs. There was less than 10% variation in the percentages quoted from each group. GLC analysis indicated that the total PG and thromboxane content is 1.3–1.8 µg per guinea pig.

§Major geometric isomer.

Table 1 lists the relative amounts of the PGs and thromboxanes observed, along with their chromatographic elution characteristics.

Very little PGE_2 or $PGF_{2\alpha}$ were detected, although there was a significant amount of 15-oxo-$PGF_{2\alpha}$ and 15-oxo-13,14-dihydro-$PGF_{2\alpha}$. A high proportion of the content occurred as compound 2, perhaps indicating a significant formation of thromboxane B_2. Hamberg[10] described the release of thromboxane B_2 after challenge in a chopped lung system and our data would suggest that *in vivo*, thromboxane B_2 may be metabolised rapidly within the cells after its synthesis and in the lung system, at least, may not exert its full pharmacological action.

The biological activities of compounds 1 and 2 have been compared with those of $PGF_{2\alpha}$ and thromboxane B_2 on a variety of smooth muscle preparations *in vitro*. Compound 2 had no detectable activity, whilst thromboxane B_2 had minimal and variable activity only on respiratory smooth muscle (1/100–1/1000 that of $PGF_{2\alpha}$).

Compound 1, however, had considerable biological activity, being 1/3 as active as $PGF_{2\alpha}$ on respiratory smooth muscle and having 1/5 to 1/100 the activity on a variety of intestinal smooth muscle preparations. Compound 1 occurs as approximately 11% of the total PGs released on challenge ($PGF_{2\alpha}$ 0.6%) and probably accounts for a significant proportion of the PG spasmogenic activity.

Only three of the compounds listed in Table 1 have significant spasmogenic activity: $PGF_{2\alpha}$, 15-oxo-$PGF_{2\alpha}$ (ref. 11) and 6-oxo-$PGF_{1\alpha}$ and the activity of the last two seems to be reasonably selective for respiratory smooth muscle. It would seem, therefore, that the identification of this novel PG (compound 1) is of considerable relevance to the immunological reaction in guinea pigs and may relate to the symptomology of human asthma.

Although there is no evidence in the present study for metabolic conversion of thromboxane B_2 to compound 2, by inference from the metabolism of the parent PGs, it seems likely that this is its probable mode of formation. The activity of the enzymes responsible for these metabolic reactions in asthmatic individuals could, therefore, be of considerable importance in an analysis of the role of PGs and thromboxanes in asthma.

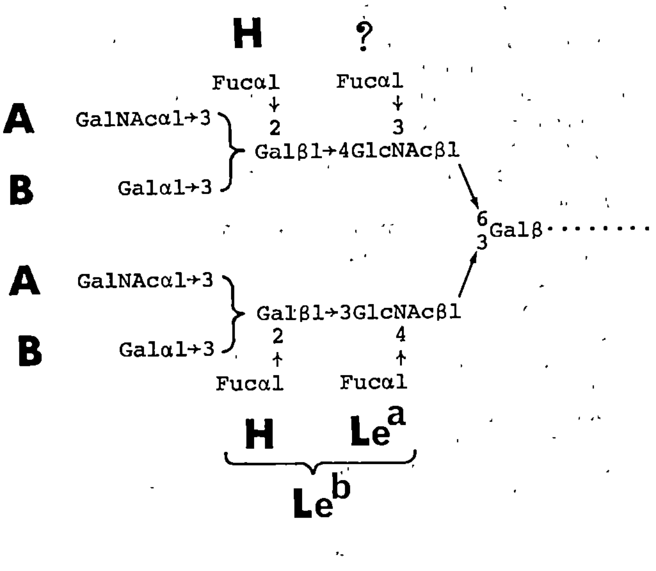
ABO blood group determinants with branched cores

Although the biochemical basis of ABO and Lewis blood types in man has on the whole been elucidated[1], more detailed information is needed about the carbohydrate structures of the A and B subgroups[2]. But investigation has been limited by the complexity of the sugar chains of these antigens[3]. Information can, however, be obtained from the study of human milk oligosaccharides, which are synthesised by a series of glycosyl transferases which mediate the formation of glycoproteins, especially those of blood group substances[1]. Our studies have shown that, contrary to the composite structures of ABO and Lewis blood group determinants described by Lloyd and Kabat[3] (Fig. 1), the H determinant is located only on the type 1 carbohydrate chain (Galβ1→GlcNAc....) of the branched sugar grouping.

Lacto-*N*-hexaose, a branched oligosaccharide with the same structure as the distal portion of the backbone carbohydrate chain of blood group substances, and its fucosyl derivatives have been found in human milk[4,5]. We have isolated three of them which have the Fucα1→2Gal grouping and elucidated their structures (Fig. 2). Details of structural studies will be published elsewhere.

Fig. 1 Composite structure of the blood group determinants proposed by Lloyd *et al.*[3].



A survey of these structures suggested that the Fucα1→2Gal grouping is limited on the type 1 chain of the branched portion of the backbone, in contrast to the widely accepted idea that the grouping occurs both on type 1 and type 2 chains of the branched core[6]. To verify this concept, the possible occurrence of even a minor isomeric component that has the Fucα1→2Gal grouping on the type 2 chain had to be eliminated. An *N*-acetylgalactosaminyl transferase (A enzyme) found in the milk of women with blood type A transfers *N*-acetylgalactosamine from UDP-GalNAc to the C3 position of the galactose residue of both Fucα1→2Galβ1→3GlcNAc.... and Fucα1→2Galβ1→4GlcNAc.... groupings[7,8]. With UDP-*N*-^{14}C-acetylgalactosamine as a donor, this enzyme can be used to detect specifically the H determinants with type 1 and type 2 chain backbone[9].

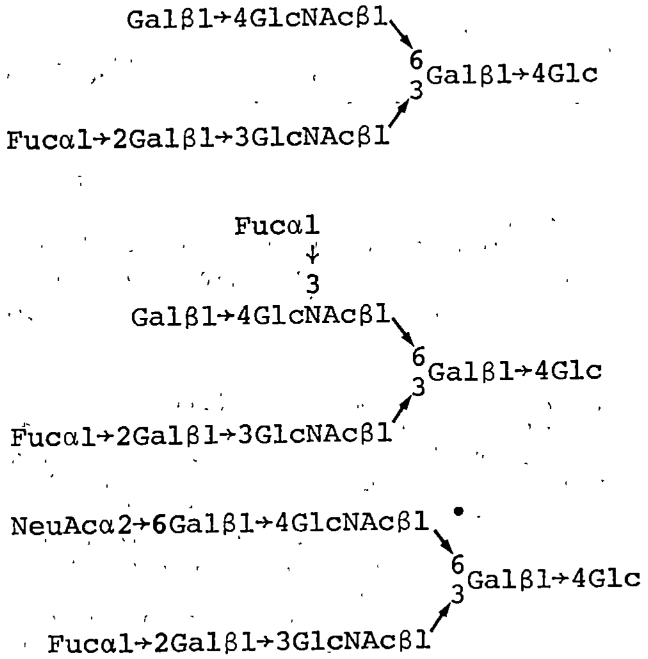


Fig. 2 Structures of three lacto-*N*-hexaose derivatives with blood group H determinant.

An endo-β-galactosidase, purified in our laboratory from *Diplococcus pneumoniae*, hydrolyses the blood group A determinant of type 2 chain but not of type 1 chain[10]. A combination of these two enzymes thus provides a sensitive method to discriminate type 1 and type 2 H determinants in heterosaccharide chains as indicated in Fig. 3.

N-2, a mixture of monofucosyllacto-*N*-hexaoses, and N-3, a mixture of difucosyllacto-*N*-hexaoses, were isolated from milk of four secretor individuals as before[11]. Each oligosaccharide was incubated with UDP-*N*-^{14}C-acetylgalactosamine and A enzyme[12], and the products were analysed by paper chromatography. A radioactive octaose was detected in all the incubation mixtures of N-2 fractions and a nonaose in all the mixtures of N-3 fractions (Table 1). When the N-2 and N-3 fractions were incubated with 20 μg of *Bacillus fulminans* α-L-fucosidase[13], which cleaves only the Fucα1→2Gal linkage, no radioactive products were detected. We conclude that the *N*-acetylgalactosamine incorporated into oligosaccharides was catalysed by the A enzyme.

The radioactive octaose and nonaose were eluted from the paper chromatogram, incubated with endo-β-galactosidase, and the release of GalN-^{14} C-Acα1→3Gal2←1αFuc was determined

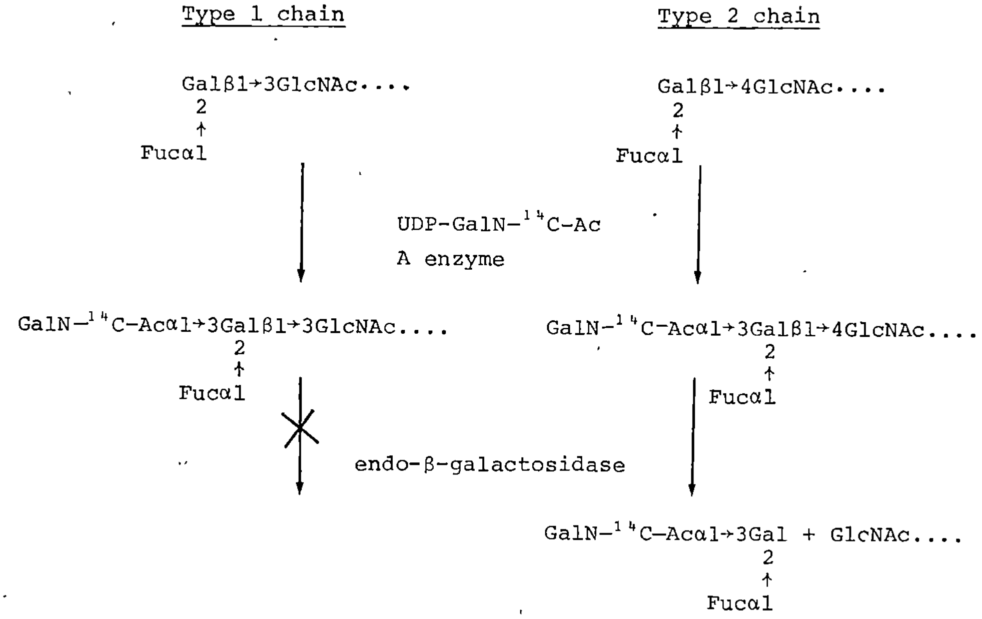

Fig. 3 Enzymatic discrimination of type 1 and type 2 H determinants

as described in the legend of Table 1. No radioactive trisaccharide was observed. Lacto-*N*-fucopentaose I and Fucα1→2Galβ1→4GlcNAcβ1→3hexene-1,2,5,6-tetrol as standards of type 1 and type 2 H determinants, respectively, were treated in the same way. Similar levels of *N*-acetylgalactosamine were incorporated into both oligosaccharides by incubation with A enzyme and UDP-*N*-^{14}C-acetylgalactosamine (Table 1). The activity incorporated into Fucα1→2Galβ1→4GlcNAcβ1→3-hexene-1,2,5,6-tetrol was recovered completely as GalNAcα1→3Gal2←1αFuc by the subsequent endo-β-galactosidase digestion, while that of lacto-*N*-fucopentaose I remained unhydrolysed (Table 1). These results confirm that the Fucα1→2Gal groupings of N-2 and N-3 fractions are located only on the type 1 chain of lacto-*N*-hexaose. The limited location of the Fucα1→2Gal grouping may be the reflection of the specificity of the *H* gene-associated α-2-L-fucosyltransferase. This enzyme adds α-fucosyl residues at the C-2 position of the non-reducing terminal galactose units of both type 1 and type 2 groupings when these are present on unbranched sugar chains[14,15]. This enzyme, however, may not be able to add a fucosyl residue at the Galβ1→4GlcNAc grouping of the branched core.

Table 1 Incorporation of *N*-^{14}C-acetylgalactosamine into oligosaccharides catalysed by A enzyme and their degradation by endo-β-galactosidase

Olgosaccharides	Gal*N*-^{14}C-Ac incorporated (c.p.m. $\times 10^{-3}$)	Counts released as trisaccharide (c.p.m. $\times 10^{-3}$)
N-2 fraction		
1	2 1	0
2	1.9	0
3	0.8	0
4	0.9	0
N-3 fraction		
1	4.8	0
2	2.9	0
3	3.2	0
4	1.8	0
Lacto-*N*-fucopentaose I	7.4	0
Fucα1→2Galβ1→4GlcNAc β1→3 hexene-1, 2, 5, 6-tetrol	6.8	6.7

A sample (50 µg) of each sugar was mixed with 300 U of purified A enzyme, 20 nmol (0 1 µCi) of UDP-*N*-^{14}C-acetylgalactosamine and 50 µl of 0.05 M Tris-HCl buffer, *p*H 7.5, containing 0.02 M $MnCl_2$. The A enzyme was obtained from the milk of an A_1 individual. After addition of a drop of toluene, the mixtures were incubated at 37 °C for 42 h. The reaction mixtures were then passed through a small column (0.5×4 cm) containing a mixed bed of BioRad AG-3 (OH^-) and BioRad AG-50 (H^+), and washed with five bed volumes of distilled water. Eluate and washings were combined, spotted on Whatman No. 3MM paper as a 3-cm band and subjected to descending paper chromatography using ethylacetate-pyridine-acetic acid-water (5:5:1:3) as a solvent for 14 d Radioautoscanning revealed a single radioactive octasaccharide and a single radioactive nonasaccharide in the incubation mixtures of N-2 and N-3 fractions, respectively. Radioactive GalNAcα1→3Gal(2←1αFuc)β1→3GlcNAcβ1→3Galβ1→4Glc and GalNAcα→3Gal(2←1αFuc)β1→4GlcNAcβ1→3-hexene-1, 2, 5, 6-tetrol were detected as the sole reaction products in the incubation mixtures of lacto-*N*-fucopentaose I and Fucα1→2Galβ1→4GlcNAcβ1→3-hexene-tetrol, respectively. These radioactive oligosaccharides were recovered from the paper chromatograms by elution with water, and the radioactivities were determined by a Packard Tri-Carb liquid scintillation spectrophotometer, after mixing aliquots of each sample with scintillation cocktail. The remaining samples were incubated with 1.0 mU of purified endo-β-galactosidase for 24 h. The incubation mixtures were spotted on Whatman No. 3MM paper, and subjected to descending paper chromatography using ethylacetate-pyridine-water (12:5:4) as a solvent for 20 h. The areas corresponding to authentic GalNAcα1→3Gal2←1αFuc (ref. 9) were cut out from the chromatogram, placed in scintillation vials, and the radioactivities were determined after incubating the paper pieces with 1 ml of water and adding 7 ml of scintillation fluid.

The Galβ1→4GlcNAcβ1→6Gal . . . . grouping has been shown to be one of the I blood group determinants[16,17]. Absence of the H blood group determinant on this grouping means that the ABO blood group system does not interfere with the phenotypic expression of the *I* gene, and that the I antigen may be able to coexist with A, B or H antigen on the same branched heterosaccharide core.

Lead competitively inhibits calcium-dependent synaptic transmission in the bullfrog sympathetic ganglion

Many polyvalent cations have been used in studies of synaptic transmission either as tools for gaining a better understanding of synaptic processes or, in their own right, as potentially toxic substances[1–7]. Inorganic lead although long known to have neurotoxic effects, has not been studied extensively at the synaptic level until recently. Kostial and Vouk[8] found that lead blocked transmission in the perfused superior cervical ganglion of the cat *in vitro* by reducing the amount of acetylcholine released from presynaptic nerve terminals without affecting the response of ganglion cells to applied acetylcholine. The addition of excess calcium to the perfusion solution restored acetylcholine output and relieved the lead block. Manalis and Cooper[9], working with the frog sciatic nerve–sartorius muscle preparation *in vitro*, showed that lead depresses phasic transmitter release evoked by nerve stimulation and increases spontaneous release as evidenced by an increase in frequency of miniature endplate potentials. Lead had only a weak, curare-like effect on the postsynaptic response to applied acetylcholine. In this paper we show, using electrophysiological techniques, that $PbCl_2$ blocks synaptic transmission presynaptically by competitive inhibition of calcium. In support of this data, we further show, using ^{45}Ca, that lead in fact does reduce the uptake of calcium by preganglionic nerve terminals.

In all experiments the 9th or 10th sympathetic ganglion was removed from the bullfrog (*Rana catesbeiana*) along with several cm of preganglionic trunk and postganglionic ramus and connecting spinal nerve. After removal of the connective tissue sheath, the ganglion was placed in a sucrose gap chamber similar to that described by Koketsu and Yamamoto[10]. This chamber allowed for the selective perfusion of the ganglion with normal or modified Ringer's solutions. Supramaximal stimuli were applied at a rate of 1 s^{-1}. Control ganglionic compound action potential was measured after 30 min of stabilisation in normal Ringer. Then the ganglion was perfused for 30 min with Ringer's solution containing lowered calcium, added lead, or both. Control and experimental periods were alternated in this way for the duration of an experiment.

Data for 4 concentrations of lead at several calcium concentrations are presented in Fig. 1. Figure 1*a* shows that the log of ganglionic response amplitude is a positive linear function of the log of calcium concentration between 0.2 and 1.0 mM. Lead shifts the response to the right with no appreciable change in slope. The slopes of the log–log curves are similar to those obtained for cobalt and magnesium at the neuromuscular junction[1,11]. The same data replotted on modified Lineweaver–Burk coordinates as described by Dodge and Rahamiandmoff[11] are shown in Fig. 1*b*. These curves intercept with the ordinate at the same point, indicating a competitive antagonism of calcium by lead. The potency of lead as a synaptic blocking agent is great when compared with magnesium, cobalt, and manganese, all of which have been shown to interfere with synaptic transmission at the frog neuromuscular junction through a competitive antagonism of calcium. Cobalt and manganese are 20 times[1,2] and lead is 1,000 times[9] more potent than Mg at the frog neuromuscular junction. Our data reported here are in general agreement since lead is at least 200 times more effective than magnesium in blocking ganglionic transmission[3].

Several other parameters were examined to ascertain whether the sole effect of lead at these concentrations was through an antagonism of the action of calcium at presynaptic nerve terminals. Axon conduction amplitude and velocity in the preganglionic nerve trunk were measured before and after exposure to lead in a concentration which completely blocked ganglionic transmission. No changes were seen. Presynaptic spike amplitude was measured by the method of Dunant[12]. Again, lead had no appreciable effect. Ganglionic response to bath-applied acetylcholine as described by Koketsu and Yamamoto[10] was used as a test of postsynaptic receptor function. Only a 5% decrease in response was observed at levels of lead which completely block synaptic transmission.

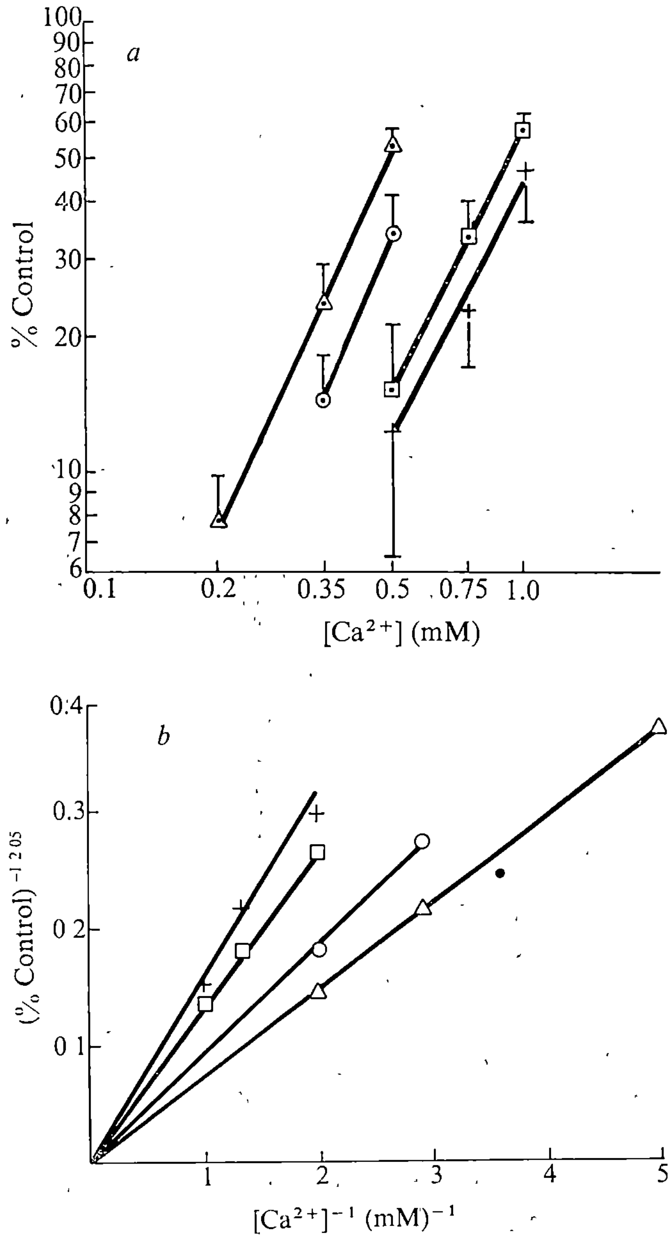

Fig. 1 *a*, A log–log plot of postganglionic response amplitude against Ca^{2+} concentration for 0, 5, 10, and 20 μM Pb^{2+}. The average slope of the lines is 2.05. Each point is the average of at least 5 determinations. The standard error of the mean is shown with each point. *b*, The same data plotted on modified Lineweaver–Burk coordinates. Control Ringer contained 111 mM NaCl, 2.5 mM KCl, 2.0 mM CaCl and 4 mM Tris buffer. All straight lines were determined by least-squares regression. Concentration of Pb^{2+} in modified Ringer's solution: △, 0 μM; ○, 5 μM; □, 10 μM; +, 20 μM.

From the data presented above we infer that lead competitively inhibits calcium-mediated transmitter release from presynaptic nerve terminals. Additional support of this conclusion was obtained in a series of experiments in which the effects of lead on the uptake of ^{45}Ca by presynaptic nerve terminals were examined. The method of Blaustein was used with several minor modifications[13]. ^{45}Ca was added to a bath containing a pair of ganglia. One member of the pair was stimulated supramaximally for 20 min at a rate of 6 stimuli s^{-1}. After rinsing, weighing, and digestion, the amount of ^{45}Ca taken into the ganglia was measured by conventional scintillation counting.

Figure 2 shows that stimulation of the preganglionic nerve resulted in a threefold increase in ^{45}Ca uptake. Antidromically stimulated ganglia took up no more ^{45}Ca than unstimulated ganglia indicating that the activity of ganglion cells and postganglionic axons did not contribute to the ^{45}Ca uptake. Furthermore, ganglia blocked by (+)-tubocurarine took up quantities of ^{45}Ca comparable to the uptake of unblocked preparations suggesting that postsynaptic receptor activity was not contributory. The ^{45}Ca uptake of stimulated lead-blocked ganglia was however, reduced to 9% of control, indicating that lead strongly blocks the uptake of calcium normally associated with the arrival of action potentials at the presynaptic nerve terminals. This is in agreement with the data and the conclusion derived from the electrophysiological studies. In addition, lead reduced the ^{45}Ca uptake of unstimulated ganglia to 16% of unstimulated control indicating an effect of lead on calcium exchange which is not related to the presence of an action potential.

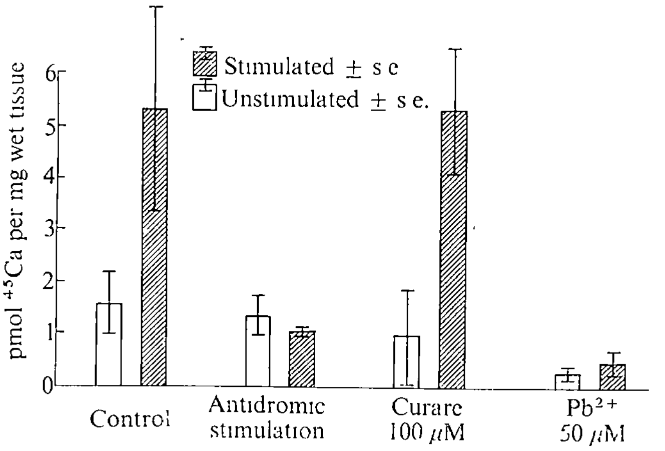

Fig. 2 The amount of ^{45}Ca taken up by ganglia under the following conditions: *a*, unstimulated ganglia and ganglia activated by preganglionic nerve stimulation, both in normal Ringer's solution; *b*, unstimulated ganglia and ganglia activated by stimulation of the postsynaptic nerve, both in normal Ringer's solution; *c*, unstimulated ganglia and preganglionically stimulated ganglia in Ringer's solution containing 100 mM (+)-tubocurarine; *d*, unstimulated and preganglionically-stimulated ganglia in Ringer's solution containing 50 μM Pb^{2+}. 50 μM Pb^{2+} blocks 100% of the postganglionic response. Modification of Blaustein's method was as follows: 5 μCi of ^{45}Ca in 50 μl HOH were added to a bath containing 2.5 ml of Ringer's solution. After stimulation, the pre- and postganglionic nerves were removed and the ganglia blotted on filter paper. Wet weights were then taken. Digestion was done in 0 5 ml of 10% tetramethyl ammonium hydroxide heated to 90 °C for 20 min. 5 ml of Bray's solution were then added for conventional scintillation counting.

From these experiments we conclude that lead blocks synaptic transmission in the sympathetic ganglion by competitive antagonism of spike-evoked entry of calcium into presynaptic nerve terminals and a subsequent reduction of transmitter release. It is not possible to say whether such a mechanism contributes significantly to the central or peripheral nervous system dysfunction seen in acute or chronic lead poisoning. Carroll *et al*[14] have, however, shown that K-induced release of acetylcholine from brain slices of mice exposed to lead during developent is reduced and is also dependent on the presence of calcium in the medium. Since the presently accepted upper limits of normal, "safe", blood lead levels of human children and adults are 2 μM and 4 μM respectively[15], it may well be that the mechanism described here is a factor in chronic lead poisoning.

Type of sensory nerve fibre sprouting to form a neuroma

WHEN a peripheral nerve is cut across, the axons in the central end send out sprouts. If these sprouts fail to reach the distal part of the cut nerve they form a tangled mass called a neuroma[1]. Neuromas which occur in man after amputation or after failure of regeneration of a damaged nerve are always tender on pressure and are sometimes the source of ongoing pain[2]. When experimental neuromas are stimulated, it is known that a delayed volley of nerve impulses arrives at the central nervous system[3] and it was assumed that the delay was occurring in the fine sprouts. Now that we have examined single fibres originating from a neuroma, we find that this conclusion was wrong and that there is a much more surprising explanation: only the small diameter, slowly conducting axons within the peripheral nerve seem to send sprouts into the neuroma and the delay in arrival of the afferent volley is primarily due to the fact that it runs only in slowly conducting fibres. This selective outgrowth of small fibres may be of considerable practical interest. These fibres include those which normally carry signals from injured tissue. In the normal situation, however, injury detection signals are accompanied by impulses in large diameter nerve fibres which decrease the central effect of the injury signals. The neuroma, as a pure culture of small fibres, may generate pain producing impulses[3] where the pain has an intensity and peculiarly unpleasant quality due to the absence of the normal modulating impulses[4] in the larger fibres which have failed to regenerate.

The experiments were carried out on 70 adult male albino rats, Sabra strain, weighing more than 300 g at the time of nerve section. Under ether anaesthesia, the sciatic nerve of one leg was transected and the central stump was drawn by a strand of epineurium into a polythene tube so that the nerve fitted snugly without compression. The end of the tube was usually capped with bone wax. Some nerves were studied in an acute preparation immediately after cutting, and others were studied 1 d to 6 months after section. For this examination the animals were anaesthetised with urethane or Nembutal, paralysed with Flaxedil, and had the lumbo-sacral spinal cord exposed. To record compound action potentials, a low lumbar dorsal rootlet originating in the neuroma was cut centrally and placed on a pair of Ag–AgCl recording hooks. For single units, fine filaments, about 20 μm in diameter and 1–2 mm long were stripped from the end of the root, placed on a single hook, and recordings made with reference to a nearby indifferent electrode. The sciatic nerve was exposed and the neuroma freed from its tube.

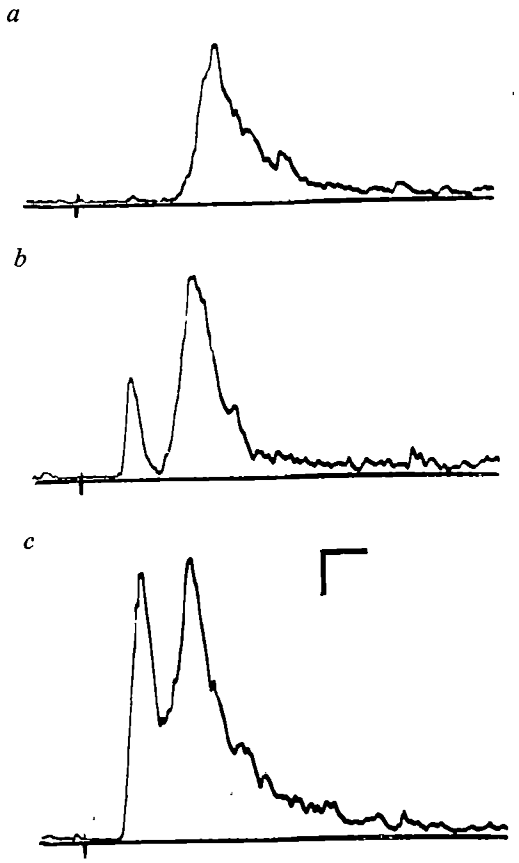

Fig. 1 Compound action potentials recorded on an L5 dorsal root following stimulation of a sciatic nerve neuroma (*a*), a point on the proximal edge of the neuroma (*b*), and a region of relatively intact sciatic nerve (*c*). Recordings were made 52 d after the sciatic nerve had been cut. The neuroma was 4 mm long. Stimulus points for *a*, *b* and *c* were 2.5, 7.5 and 12.5 mm central to the distal end of the neuroma. A cathodal square wave pulse (2.0 mA, 0.05 ms) was delivered at the point indicated in each sweep. The calibration marks are 1 ms and 200 μV negative upwards. The results show that only a slowly conducting wave was produced from the neuroma while a bimodal compound action potential was evoked by stimulation only slightly proximally on the nerve.

The exposed surface of the neuroma and nerve was then stimulated at selected points by silver hook or mono- or bipolar fine tungsten electrodes delivering square wave pulses of 0.01–0.5 ms duration from a constant current source.

By one week after the nerve had been cut, an obvious swelling appeared on the end. When this was stimulated at a current adequate to stimulate intact nerve, no response was recorded. If the stimulus was increased, a compound action potential appeared on the root after an unusually long delay. An example is shown in Fig. 1*a* where the nerve was examined 52 d after section and the stimulus applied midway along the 4-mm neuroma. Using the same intensity of stimulus, compound action potentials were also evoked by stimulation at points 5.0 mm (Fig. 1*b*) and 10.0 mm (Fig. 1*c*) proximally along the nerve. It will be seen that the compound action potential evoked from 10.0 mm proximal to the neuroma has two peaks and arrives in 0.8 ms. The wave evoked from the neuroma itself, only 10 mm distally, however, takes an extra 1.4 ms to arrive. Similar results were seen in all nerves tested from a few days to 6 months after section. The extent of the delay depended on the survival time with delays increasing for about 3 weeks. Thereafter, little further slowing occurred. The question of whether this delay is due entirely to slowing of spike conduction within the neuroma or to the possibility that only slowly conducting parent fibres penetrate the neuroma was only settled with certainty by single unit studies.

Single fibres originating from the neuromas were examined by recording from fine dorsal root filaments and by stimulating at two locations, one (S_1) on the intact nerve, usually about 20 mm from the neuroma, and one (S_2) on the neuroma itself (Fig. 2, top). The two stimulus locations allowed the single unit nature of the spike to be defined by the collision technique. First a unit driven from the neuroma was identified and its latency measured and conduction velocity (S_2 velocity) calculated. Then a shock was applied to the proximal stimulating electrode (S_1) 0.5–10 ms before the neuroma stimulus, and its intensity raised gradually. Suddenly the spike originating in the neuroma vanishes and is replaced by an earlier identical spike. The proximal stimulus has generated an orthodromic spike which is recorded and an antidromic spike which has collided with the spike originating from the neuroma, abolishing it (Fig. 2). The latency of the spike from the S_1 stimulus can now be measured and the conduction velocity of the fibre from the S_1 position to the recording electrode (S_1 velocity) calculated. This technique allowed single myelinated and unmyelinated afferents to be identified and

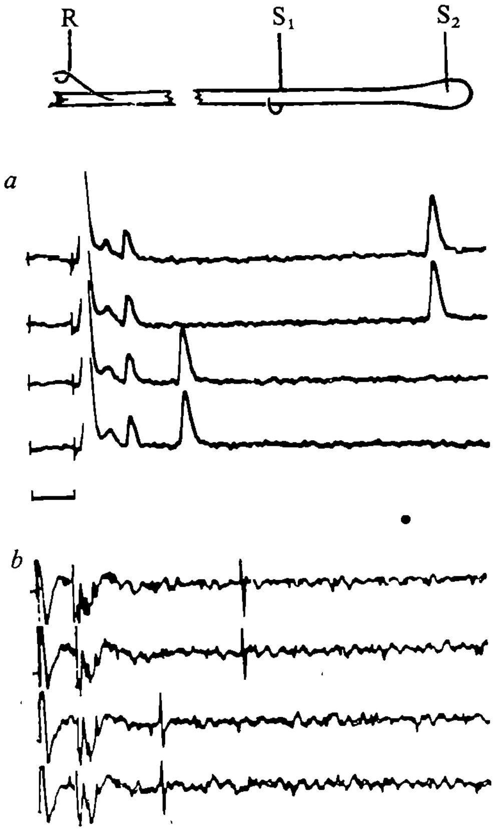

Fig. 2 Single units identified by the collision technique. The recording and stimulation arrangement is shown in the diagram at top. *a*, Top sweep, S_1 stimulus is delivered at the beginning of the sweep and evokes a volley of spikes (compound action potential) on the dorsal root filament from 1–2 ms after the stimulus. The S_2 stimulus is given 1 ms after the S_1 stimulus and it evokes a single spike with a latency of 7.9 ms seen on the right of the sweep. The stimulus current on S_1 is increased in the second sweep but is still below threshold for the single unit. In the third and fourth sweeps, the strength of the S_1 stimulus has reached the unit's threshold and a spike now appears 3.3 ms after the S_1 stimulus. This spike has the same height and slope as the one evoked by the S_2 stimulus in the sweeps above. When the spike is produced by the S_1 stimulus it collides with the spike produced distally in the neuroma (S_2) so that the spike produced from S_2 cannot travel to the recording root. This proves that the action potential from the two stimulus points occupied the same fibre. The overall conduction velocity from S_1 was 24.8 m s^{-1} and from S_2 was 11.9 m s^{-1}. *b*, Using the same procedure as in *a*, a single unit with a lower conduction velocity was identified. Here the S_1–S_2 time difference was 10 ms and the overall conduction velocity was 2.2 m s^{-1} from the S_1 stimulus point and 2.2 m s^{-1} from the S_2 point. The time mark is 1 ms for *a* and 10 ms for *b*.

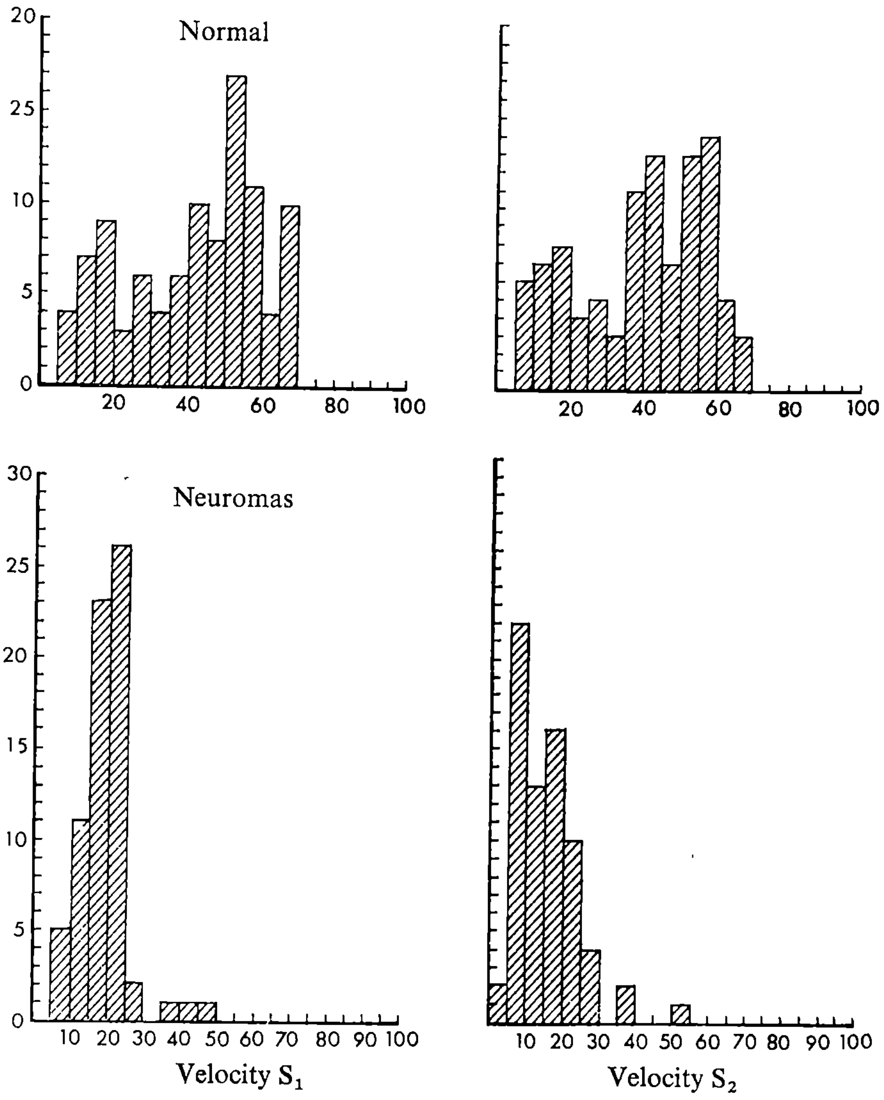

Fig. 3 Histogram of conduction velocities of 99 successively encountered single fibres in normal nerves and of 70 originating from neuromas of 50–84 d standing. The recording and stimulus situation is shown in the diagram in Fig. 2. For normal fibres, the sciatic nerve was intact and the stimulus points were at the standard positions used in the neuroma animals. The conduction velocity of each single fibre was calculated, using the collision method, both for the S_1 stimulus position on proximal nerve and for the S_2 position at the neuroma. It will be seen that virtually all impulses elicited by electrical stimulation of the neuroma run in fibres which have a low conduction velocity in the proximal nerve. Only sprouts of slowly conducting fibres appear to contribute to the neuroma. The velocities from S_2 are slower than those from S_1 because there has been a slowing of the impulses in the fine sprouts within the neuroma.

allowed the calculation of conduction velocities both for the parent fibre alone and its extension into the neuroma.

In a series of unoperated rats, and rats with sciatic neuromas, this was done for every unit encountered from the S_2 stimulus position that was sufficiently well isolated to allow for unequivocal determination of its velocity also from the S_1 position. The histogram of S_2 conduction velocities in normal nerves (Fig. 3, upper right) shows a distribution ranging from 5 m s^{-1} up to 80 m s^{-1} with the expected bimodal distribution. The histogram for S_1 velocities of these same fibres is very similar (Fig. 3, upper left) since normal fibres have relatively uniform velocities along most of their course. The histogram of conduction velocities from the neuroma shows, however, that almost all the units sampled from neuromas had slow overall velocities (Fig. 3, lower right) and furthermore their parent fibres in the intact part of the nerve were also slow (Fig. 3, lower left). In addition to the small myelinated fibres whose sprouts make up the neuroma, a number of unmyelinated parent fibres were observed which extended into the neuroma. These fibres, which may have a role in pain along with the small myelinated fibres, will not be discussed further here. They were not included in the histograms because they were specifically sought and not randomly encountered as was the rest of the sample.

Most of the fibres from neuromas had overall (S_2) conduction velocities somewhat slower than the velocities of their parent fibres (Figs 2*a* and 3, bottom). This difference undoubtedly represents a slowing of the impulses in the tangled fine sprouts within the neuroma. In a few fibres one S_2 response latency was observed when near-threshold stimulating currents were used, but when the current was increased the unit's response latency suddenly jumped to a smaller value. Apparently, the stimulus had now become suprathreshold at a slightly more proximal position on the sprout. For each spike initiation point within the neuroma, however, the parent fibre velocity measured at S_1 was identical. It has been reported that there is a slight shrinkage of myelinated fibres proximal to a nerve section[5], a phenomenon reflected in the slight slowing of the fast component of the compound action potential elicited from positions proximal to neuromas as compared with an intact nerve. This change however, is quite inadequate to explain the marked low velocity of the parent fibres of neuroma sprouts.

These data indicate that electrical stimulation of neuromas formed on the transected sciatic nerve activates slowly conducting myelinated (A-delta) but not more rapidly conducting myelinated fibres. This presumably means that only small fibres sprout to form a neuroma. Alternatively, it may be that large fibres also emit sprouts but that orthodromic conduction along them is blocked, perhaps because the fine sprout is unable sufficiently to depolarise the large parent axon[6].

Swimming in the sea anemone *Stomphia coccinea* triggered by a slow conduction system

THERE has been great interest in the sea anemone *Stomphia coccinea* since its remarkable swimming response to the starfish *Dermasterias imbricata* was first discovered[1]. On contact with *Dermasterias*, this anemone rapidly detaches from the substrate and undergoes a series of swimming movements involving flexions of the column. The starfish *Hippasteria spinosa*[2] and a nudibranch, *Aeolidia papillosa*[3] also evoke swimming. Previous attempts to analyse this response physiologically were based on indirect observations of swimming induced by electrical stimulation. There were difficulties in explaining the coordination of the swimming response in terms of a single nerve net and it has been suggested that the swimming response is controlled by a separate system[4]. The electrical activity from sea anemones can be measured and correlated with various behaviour patterns[5,6]. Use of these techniques with *S coccinea* has shown that a slow conduction system, quite distinct from the familiar through-conducting nerve net[7] always becomes active when *Dermasterias* contacts *Stomphia*. This activity, it seems, triggers the entire swimming sequence.

Polythene suction electrodes were used for both recording and electrical stimulation, as described elsewhere[8]. An electrode was attached to the tentacles of the anemone for recording purposes and the animal was harnessed (Fig. 1*a*) by pinning a sector of the oral disk of a completely intact anemone to a rigidly fixed platform of Sylgard resin. This ensured that those tentacles within the sector would be fixed in space, thereby reducing the possibility of the electrode being thrown off during swimming movement. This procedure does not unduly affect the swimming response.

A single shock (5 ms duration, 10 V intensity) delivered through a stimulating electrode attached to a tentacle evokes a response (Fig. 1*b*), detected by a recording electrode on an adjacent tentacle. Similar pulses have been recorded from other sea anemones[6,9] and seem to originate from three separate conduction systems: the through-conducting nerve net (conduction velocity up to 120 cm s^{-1}) and two slowly conducting systems, the SS1 (conduction velocity 3–14 cm s^{-1}) and SS2 (conduction velocity ~4 cm s^{-1}). The properties of these systems have been described elsewhere[6]. Activity occurring within any one system may be distinguished from that occurring in the others by comparing the conduction velocities, thresholds of excitation and characteristic waveforms of the recorded pulses (see Fig. 1*b*).

The complete swimming sequence can be triggered by bringing *Dermasterias* into contact with a single tentacle of *S. coccinea*. Previous accounts[1,2] have described the stages in this behaviour pattern as follows: (1) an "alerting" response of the entire tentacular crown on contact with the starfish; (2) temporary contraction of the upper region of the column often shielding the tentacles from view and breaking the tentacle–starfish contact; (3) extension of the column because of a gradual constriction of the mid-column region; (4) re-emergence of the tentacular crown, relaxation of the upper column region and expansion of the entire oral disk; (5) constriction of the pedal disk margin, detachment of the pedal disk from the substrate and formation of a cone-shaped projection from its centre, (6) alternating ipsilateral and contralateral flexions of the column wall constituting the swimming movements of the animal. The entire sequence, stages (1)–(6) may take ~ 5–15 s, and the swimming flexions continue, with lengthening pauses between bursts, for up to 5 min.

The electrical activity recorded from a single tentacle of the anemone at the beginning of this response is shown in Fig. 1*c*. In this instance, the starfish was placed against the tip of a single tentacle, 4.5 cm from the recording site, for 1.5 s. The evoked electrical activity was a series of pulses identified by their waveforms as originating in the SS1. There was no accompanying activity associated with the through-conducting nerve net or SS2 This was not because the recording equipment could not detect ongoing activity in these systems, since a test shock applied during the response evokes characteristic pulses in all three systems. The behavioural responses accompanying this electrical activity included stages (1)–(5); but no electrical activity has yet been recorded, either from the SS1 or any other identifiable system, during the swimming flexions (stage (6)).

The SS1 can be electrically stimulated alone by placing a stimulating electrode on an ectodermal flap cut into the column and applying shocks at an intensity above SS1 threshold[6]. With the exception of the temporary, upper-column contraction (stage (2)), the entire swimming response can be triggered by stimulating the SS1 within the appropriate frequency range; about 1 shock every 250 ms to 1 shock every 4 s. At greater frequencies, the SS1 becomes refractory and does not conduct. At lower frequencies, the

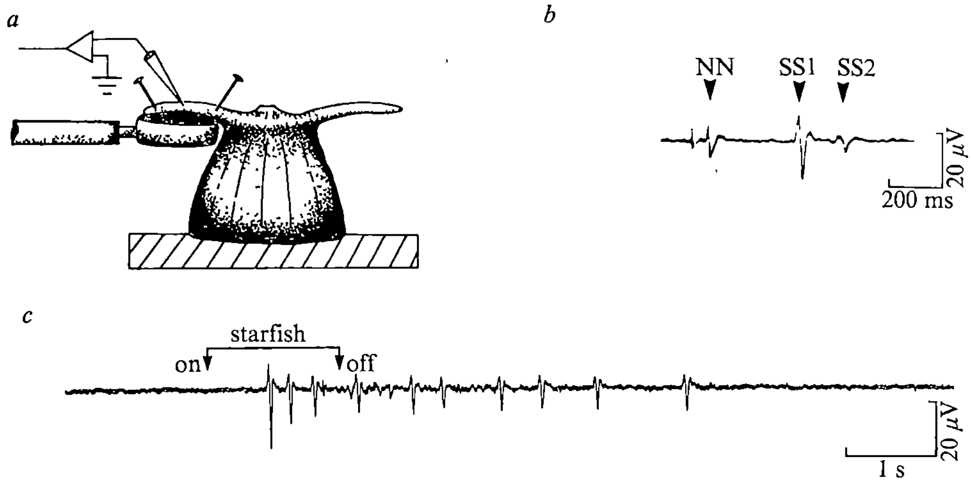

Fig. 1 *a*, *Stomphia coccinea* tethered to an immobile platform for recording purposes. A suction electrode is attached to a tentacle pinned to the platform and the pedal disk has affixed itself firmly to the substrate *b*, Electrical activity recorded from a tentacle in response to a single shock to an adjacent tentacle. The first pulse denotes the stimulus artefact. The recorded pulses are associated with three separate conducting systems: the through-conduction nerve net (NN) and two slowly conducting systems, SS1 and SS2. *c*, Electrical activity recorded from a tentacle during the initial stages of the swimming response. The starfish *Dermasterias imbricata* was brought into contact with another tentacle to initiate the response (on) and removed 1.5 s later (off). This evokes repetitive firing in the SS1.

swimming response cannot be triggered. A minimum of about 4 shocks (at a frequency of 1 shock every 250 ms) is usually required to elicit the response but more shocks were often required if the anemone had not swum within about the preceding 10 h. This indicates that the internal state of the animal may exert an influence over the activation threshold of the swimming response[10].

The through-conducting nerve net and SS2 do not seem to be involved in triggering the swimming response. Electrical stimulation of the intact column above SS1 threshold excites both the nerve net and the SS1, but in this case the swimming response may be triggered with a slight modification: the anemone sometimes contracts or 'twitches' as the shocks are applied. If the stimulus intensity is above threshold for the nerve net but below that for the SS1 so that the nerve net alone is stimulated, the anemone will contract but swimming behaviour is not triggered. This confirms and explains earlier results with electrical stimuli applied to the intact column[4] where the threshold for swimming was shown to be higher than that for contraction. The failure of electrical stimulation of the SS1 to cause the initial contraction of the column (stage (2)) that occurs in the response to *Dermasterias* is, nevertheless, puzzling. This stage in the response may be caused by mechanoreceptors[10] activating a system whose electrical activity cannot be detected by the techniques used here.

The SS1 pulses seem to constitute a sensory response to the unidentified active chemical found in *Dermasterias*[11]. This sensory response operates over a much faster time scale than comparable activity previously encountered in sea anemones. In Fig. 1*c* a total of 10 pulses occurs over a period of 4.8 s (mean inter-pulse interval (i.p.i.)=533 ms). In the response of the anemone *Calliactis parasitica* to *Buccinum* shells, the SS1 fires at a mean i.p.i. of approximately 7 s (ref. 12), and in the prefeeding response of the anemone *Tealia felina*, the same system fires at a mean i.p.i. of approximately 25 s (ref 13). Anti-facilitation of pulse amplitude occurs in addition to a process of sensory adaptation (Fig. 1*c*) phenomena also encountered in *Tealia*[13].

The SS1 coordinates pedal disk detachment in *Calliactis*[12] and it probably has a similar function in *Stomphia*, operating the entire process at a much faster rate. The observation that continuous activity of the SS1, SS2 or through-conducting nerve net is not necessary to maintain the swimming flexions suggests that the SS1 may feed into and trigger a 'swimming programme' which is maintained and coordinated by a localised motor system, perhaps the network of large multipolar nerve cells found in the column[14]. So far, however, it has not been possible to record electrical activity from this network during swimming.

These results extend the direct evidence for the view that the behaviour of sea anemones is not controlled by a single nerve net. Swimming in *Stomphia*, like the transfer of *Calliactis* to shells[12] and other complex behaviour patterns, involves interactions between different conduction systems. These findings should allow a reappraisal of current ideas about the control of behaviour and the organisation of the nervous system in these so called 'simple' animals. Species of *Stomphia*, which display a variety of specific, stereotyped and repeatable behaviour patterns, should be prime subjects in further investigations to the end.

Polarised light-sensitive interneurones in a swimming crab

THIS report shows that there are polarisation-sensitive interneurones in the crab visual system, contrary to recent speculations[1]. It also shows that polarised light information in crabs is elaborately processed.

Naturally-occurring light polarisers include water surfaces, particles suspended in air and water[2], and many larger objects, especially of biological origin (unpublished observations). Five uses of this diversity of environmental polarised light by animals have been put forward. Animals such as bees[3,4] may infer the position of the sun for navigation although the sun itself is obscured. Polarised light patterns may enable aquatic animals to detect an 'artificial horizon'. For animals flying above water surfaces this may result from the fact that reflected light is horizontally polarised[5]. In the underwater case light is polarised by reflection from suspended particles; here the area of greatest brightness is always horizontally polarised[6]. The water skater *Gerris* may use polarisation sensitivity (PS) to screen out the predominantly single plane of reflected light from water surfaces, enabling a better view into the water[7]. PS may enable extra discriminations about visual contrast through a system analogous to colour vision. This approach has been suggested for human divers[8], but has not until now been proposed as a physiological mechanism. Finally, PS in photoreceptors has been shown to enhance quantum capture and thus absolute sensitivity to light[9].

In spite of this wealth of possibility, evidence of the interneuronal processing which must underlie the behaviours listed above has been presented in only one, anomalous, case: PS interneurones have been reported in the goldfish[2]; the anomaly is that goldfish receptors exhibit no PS.

I looked for PS interneurones in the optic lobes of the eye of a swimming crab, *Scylla serrata*, an animal which has known PS in the receptors (ref. 10 and unpublished observations) (Fig. 1*a* and *b*). I used a broad field stimulator not reported before in polarised light vision research, which in some ways simulated the light environment found underwater. This paper presents evidence of PS interneurones in *Scylla*: the result does not agree with the recent suggestion that the neural wiring pattern of the crustacean eye cancels out the PS information present in the receptors, producing only a polarisation-independent system[1].

In the experiments reported here, single spots were projected from behind on to a paper diffusing screen 30 cm from the rigidly cemented left eye of a legless but otherwise intact crab. The screen measured 16×9 cm, and on it spots from 2 to 30° diameter subtended at the eye could be displayed. All stimuli were plane polarised by a 60-cm diameter rotatable disk of polaroid positioned between the screen and the eye. A 360° potentiometer mounted coaxially with the disk enabled its position, and its rate and direction of rotation, to be recorded.

In the experiments, two essential precautions were taken. The problem of spurious reflections dependent on the light source had already been recognised[11]. These were avoided

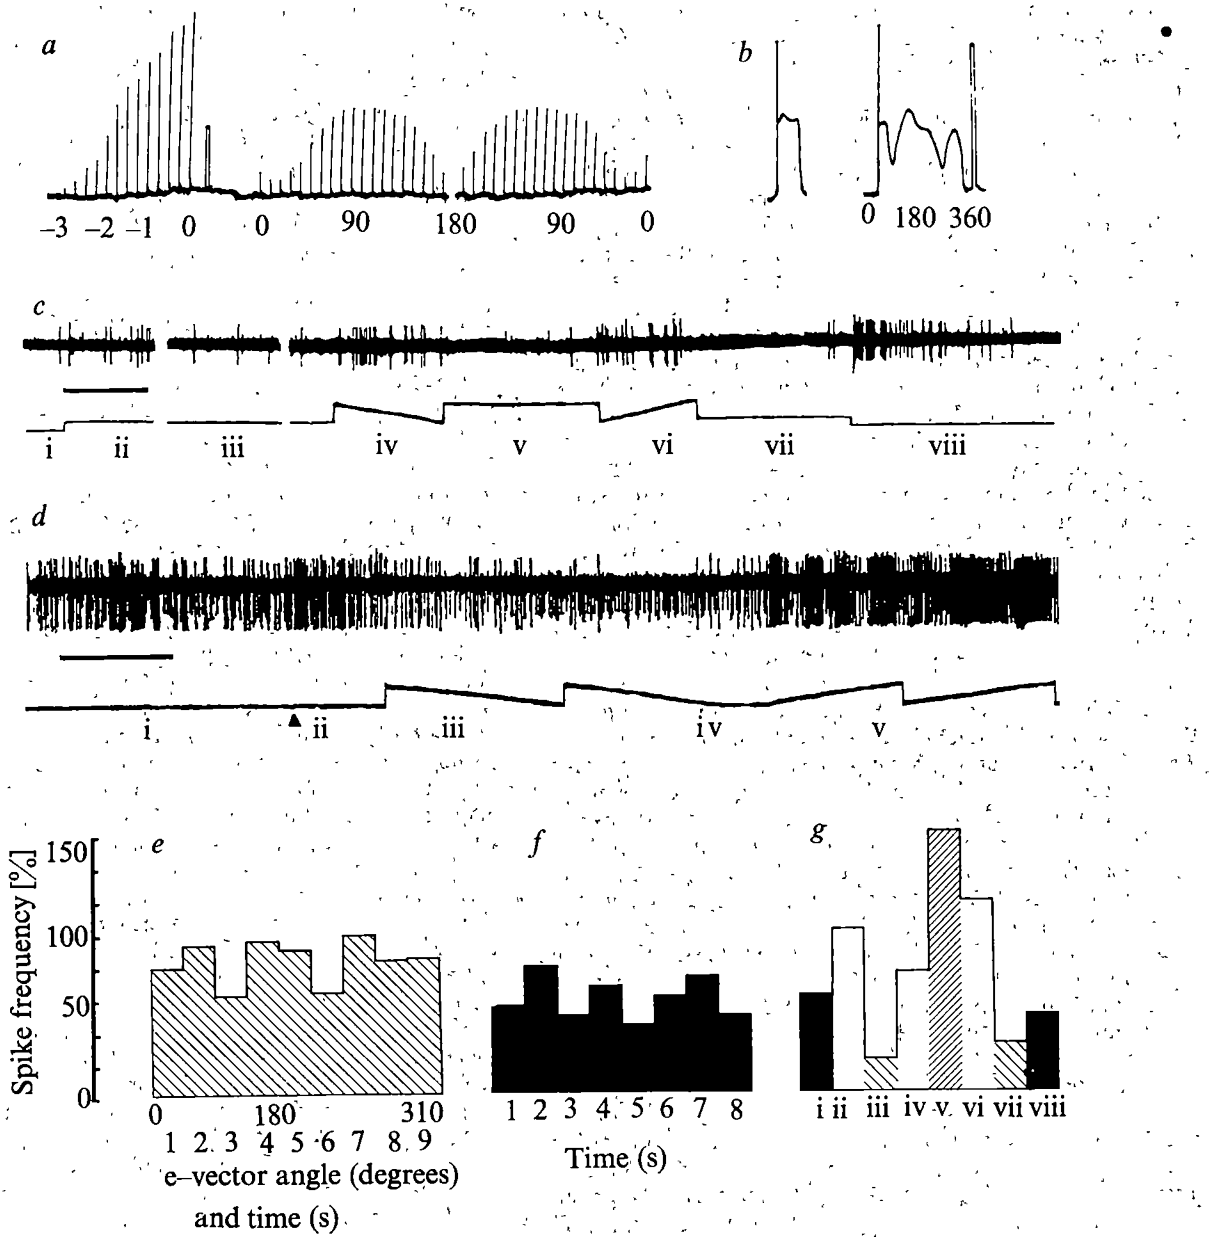

Fig. 1 *a*, Photoreceptor responses to increasingly intense flashes of light over 3 log units of intensity, and then photoreceptor responses to flashes of polarised light with the e vector moved first clockwise and then anticlockwise in 10° steps, one 40-ms flash every 5 s. Calibration 20 mV. The difference in response at maximum and minimum is equivalent to 1 log unit of intensity and thus the cell has a polarisation sensitivity of 10. *b*, Photoreceptor responses to continuous polarised light, e vector stationary and vertical, and then to continuous polarised light, e vector rotated through 360°. *c*, Interneurone I. The stimulus channel shows: i, dark discharge; ii, light-on (polaroid static and vertical); iii, response after 30 s of this unchanged stimulus; iv, polaroid rotation clockwise 360°; v, polaroid left, stationary and vertical; vi, polaroid rotation anticlockwise; vii, polaroid stationary and vertical; viii, light-off. Time mark 5 s. Note that the response is independent of stimulus direction, and that light-off has the strongest effect. *d*, Interneurone II. The stimulus channel shows: i, dark discharge; ii, dim light-on (▲) with polaroid static and vertical; iii, polaroid rotation clockwise; iv, polaroid static and vertical; v, polaroid rotation anticlockwise. Time mark 5 s. Note directional selectivity of response, and that polaroid rotation has a stronger effect than light on. *e*–*g*, Interneurone II. Data showing absence of stationary, presence of rotational PS. *e*, Response of a unit to a stimulus similar to that given the receptor cells in continuous light but 45° steps. There is no significant stationary PS as the response range is not significantly different from a similar period of dark discharge (*f*). *g*, Distinct response of three class II units to the rotational stimulus sequence (i–viii) listed above.

by placing a black screen with a small (3×2 mm) window close (2 mm) to the eye. The screen acted as a light baffle and ensured that the crab saw only the light spot and not, for example, its reflection from the floor of the preparation holder. Second, the fact that the stimulating variable really was polarised light and not intensity was checked. Measurements with a Hewlett Packard 8334A radiant flux meter showed only 0.57% intensity variation during an e-vector rotation of 360°.

Units were recorded extracellularly from the external medulla by conventional glass microelectrode techniques. Examples of two classes of unit are presented here. Both classes have very broad receptive fields, responding to test spots applied anywhere over the whole eye. For both units the experimental protocol was similar.

Unit 1 (20 cells recorded) responds to polaroid rotation, but is insensitive to the direction of rotation. In a typical trial (Fig. 1*c*, i–viii), a class I unit showed a small increase in discharge to light-on (e vector stationary and vertical). The cell was allowed to adapt to a low frequency of discharge (iii) and 30 s after light-on, polaroid rotation at a rate of about 50° s^{-1} was commenced (iv). This led to a fivefold increase in discharge rate. The opposite direction of rotation (vi) showed the same effect, and that it was independent of the orientation or direction of rotation of the **e** vector. Stopping rotation led to cessation, then a gradual return of activity.

Figure 1*d* and *e* show the responses of a class II unit which responds to both rotation *and* direction of rotation of **e** vector (6 cells recorded). Here, illuminating the spot with the **e** vector stationary and vertical, led to a doubling of discharge rate (ii). Rotating the polaroid clockwise at about 50° s^{-1} (iii) led to a progressive decrease in rate to a fifth of that induced by light-on. In complete contrast, an anticlockwise rotation (v) led to a progressive and sevenfold increase on the previous clockwise rate.

In discussing these results a point first arises as to categories of polarised light stimulus. When a polarising filter is rotated between a light source and the crab eye, the intracellular response of a retinula cell varies with the angular position of the filter (Fig. 1*a*). The commonly used definition of receptor PS has always been derived from responses to flashes of light, each being through a different stationary e-vector angle. I term this stimulus a stationary stimulus. It contrasts with the stimulus used in the interneurone experiments reported here, which I term a rotational stimulus.

The receptors of the crab eye are modulated by both stationary and rotational polarised stimuli (Fig. 1*a* and *b*). Because they respond to both, receptors by themselves cannot distinguish betwen stationary and rotational stimuli. It is clear that the interneurones demonstrated here are more specialised elements in a polarisation detection system. Both are more highly tuned to **e**-vector rotation than the receptors; furthermore, unit II is more highly tuned to rotation than unit I.

Although there are no data on the static PS of unit I, its response to rotation is quite different from that of a receptor. It has a flat response to rotation, whereas the receptor response is modulated (Fig. 1*b*).

In turn, unit II is more highly organised than unit I. First, in terms of the weighting given to intensity change relative to **e**-vector change: in unit I, the greatest response modulation was caused by light-off; in unit II, the greatest modulation was caused by **e**-vector change. Second, and most important, only unit II responds with directional selectivity.

These results demonstrate the existence of polarised light information in the crab central nervous system. The crab may use this information in three of the five ways mentioned in the introduction.

The first of these is contrast enhancement. The units reported here have been shown to respond to changes both in light intensity and in rate of **e**-vector rotation. It may be, however, that the general response is to moving patterns composed of variations in intensity and of polarisation. If this is the case visual contrast in the system could be enhanced in the following way. It is possible to imagine a grey moving object invisible against an equally grey background. If, however, the light coming from the object were different from the background in amount and **e**-vector angle of polarised light—a situation common in the ocean—the above PS system would detect a contrast difference. In this way the otherwise invisible object would become visible.

Second, orientation : in servo systems it is advantageous that rate of change detectors feed back to the output. If information from the units reported here were fed back to the motor system, *Scylla* could swim so as to minimise output from the PS interneurones and therefore move at a fixed angle relative to the polarised background. Such a system would minimise rolling and would act as a visual stabilisation system. Note, however, that units of class I and II alone would not enable a crab to orientate to one particular angle as opposed to another. This is because neither unit measures stationary **e**-vector angle. For this, a channel carrying positional information is required. This could be from the gravity detection system—in crabs, the statocysts—or from as yet undiscovered interneurones with stationary PS. Bodies of water are often turbid to the extent that swimming animals can see neither bottom nor solar position. In these very conditions, however, the polarised artificial horizon would be easily visible to an animal with the polarisation-sensitive system I have outlined. Such a system would enable animals to orientate visually in otherwise featureless water.

Finally, the underwater polarised pattern, while maintaining its horizontal component, moves with the Sun's movement during a day. If PS interneurones were allied with an internal clock, the system, as in the bee, could be used for navigation.

I thank Dr Y. Tsukahara and Dr S. Laughlin for useful discussions.

Aerial gas exchange in Australian arid-zone crab, *Parathelphusa transversa* Von Martens

Parathelphusa transversa is a brachyuran crab of the family Potamonidae and is found over much of inland Australia, including arid areas[1]. Permanent water sources, such as water holes, rivers and dams are avoided and during prolonged dry periods the animals lead a fossorial existence, their air-filled burrows being found in the clay soils of dry swamps and water courses. After heavy rain or flooding they emerge from their burrows to forage in the surface water, leading an amphibious existence. Their mode of life requires the capacity for gas exchange in both air and water and this is associated with structural adaptations of the branchial chamber to form a lung. We describe here the animal's unusual and hitherto undescribed mechanism of tidal ventilation of the lung.

Several other families of the Decapoda include terrestrial and semi-terrestrial representatives[2]. Most attention has been paid to those crabs which evolved from intertidal forms so that it is of interest to examine the parallel adaptations to air breathing which have occurred in this crab of freshwater origin.

The branchial chambers which are enclosed by lateral extensions of the carapace (the branchiostegites) are much expanded compared with aquatic forms (Fig. 1). There are seven pair of gills (a smaller number than in most aquatic crabs). These are reduced in size and only occupy a small proportion of the total volume of the branchial chambers. The remaining epibranchial spaces are normally air-filled, when the crab has access to air.

The branchiostegite is highly vascularised as in other terrestrial crabs (Figs 1–3). Blood channels between the inner and outer integument of the branchiostegites are separated by a system of connective tissue partitions, which

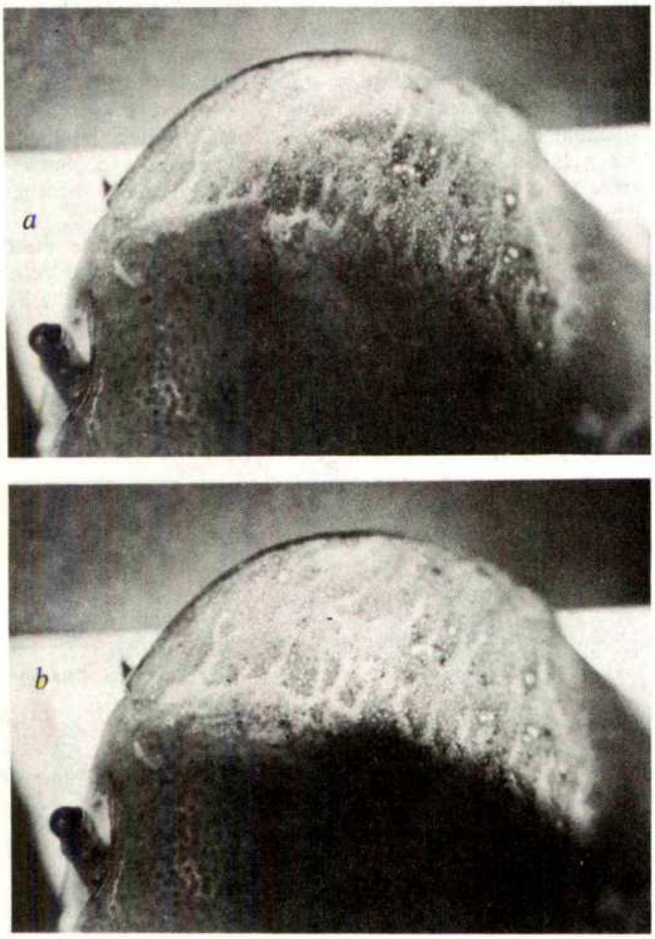

Fig. 1 *P. transversa* supported in air and illuminated strongly from the ventral side. Markings on carapace above branchial chamber delineate the major blood channels. *a*, Near-maximal expiration. Note the shadow of the thoracic wall penetrating into the branchial chamber. *b*, Maximal inspiration; thoracic wall has retracted out of the branchial chamber.

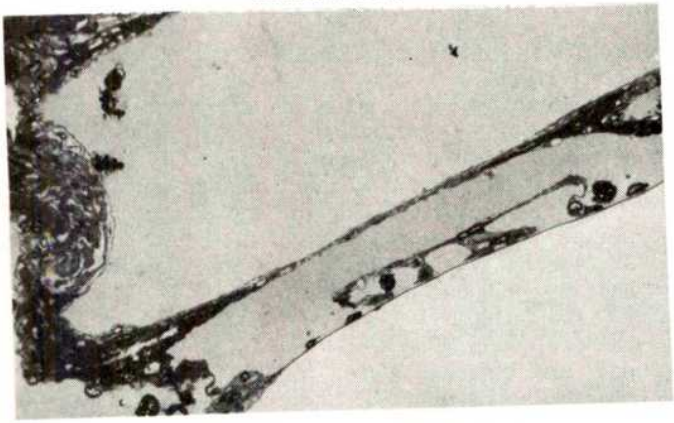
fulfil the dual role of directing blood flow and acting as a suspensory system for the inner integument. Support for this delicate membrane is presumably also provided by the hydrostatic pressure of the haemolymph.

Although the inner surface of the branchiostegite is smooth and lacks the surface amplification described in the Ocypodidae[2] and Coenobitidae[3] it is well adapted for air–blood gas exchange. The inner cuticle (Fig. 3) is extremely thin (about 0.2 μm). For comparison, the cuticle covering the gill leaflets and filaments in this and other crustaceans is generally about 1–3 μm thick (refs 4 and 5, and unpublished observations). The cuticle here seems to be represented only by a thin epicuticle[6]. There are no lamellae of helicoidally oriented chitin–protein microfibrils as seen in the exocuticle and endocuticle of the gills and other regions (ref. 6 and unpublished observations).

Fig. 2 0.5-μm epoxy section of dorsal region of branchiostegite stained with methylene blue. Extensive blood channels are partitioned by connective tissue. The thin epidermal lining of the inner cuticle (lower area) is unresolvable at this magnification (×168).



The blood–air diffusion path is further minimised by extreme attenuation of the epidermal cells underlying the inner cuticle. Except in the sparsely distributed perinuclear regions of the cells the cuticle is separated from the blood by a cellular layer only 20–100 nm thick, of which about 15 nm is represented by the apical and basal plasma membranes. The apical plasma membrane is applied directly to the cuticle. A thin (about 40 nm) basal lamina covers the haemolymph surface of the cells. Thus the total blood–gas distance is about 0.2 μm over most of the surface of the lung. This is of the same order of magnitude as the blood–gas distance in the lungs of the most active vertebrates and considerably less than in some[7].

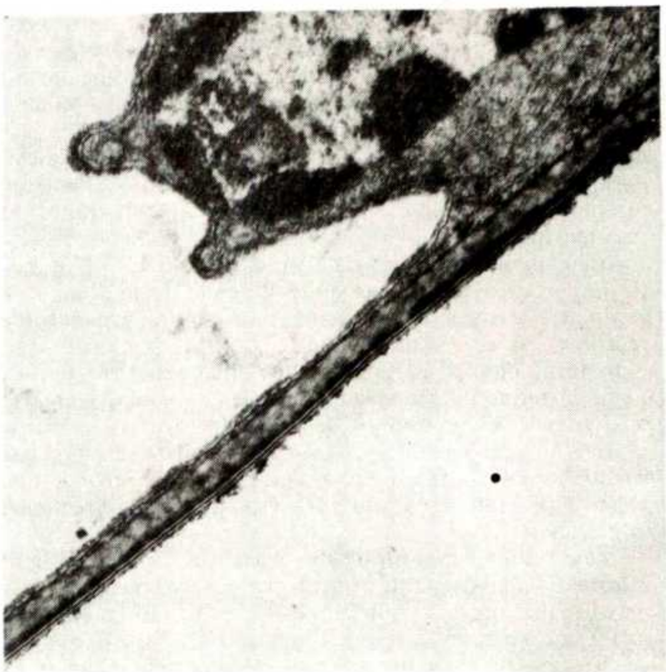


Fig. 3 Electron micrograph of inner cuticle of branchiostegite showing very attenuated extensions of the epidermal cell over the blood side of the cuticle. Formaldehyde–glutaraldehyde fixation with post-osmication (×10,500).

The mechanism of ventilation when breathing air has been examined. Surprisingly the scaphognathites, which are important in producing respiratory water currents in the aquatic mode and which are involved in aerial ventilation in other crabs[2,3,8], are not involved. Expiration is brought about by expansion of the membranous thoracic wall and roof of the branchial chamber (dorsal region of the thoracic epimera and pleura) into the epibranchial chamber (Fig. 1*a*). Inspiration is achieved by the retraction of the membrane to assume its normal concave form (Fig. 1*b*). Inspiration in one epibranchial chamber is accompanied by simultaneous expiration in the other. These movements may be observed by shining an intense light (with heat filter) through the animal from the ventral surface and observing the shadows of the thoracic wall on the carapace. This movement involves a slow lateral oscillation of the thoracic viscera (dark areas in Fig. 1*a* and *b* are probably mainly the digestive gland).

Direct observation reveals that the scaphognathites do not beat during aerial ventilation, the prebranchial apertures above the mouth remaining open. By placing detergent films over these so-called 'exhalent apertures', it was established that ventilation was tidal, both inspiration and expiration occurring through these apertures. The Milne-Edwards apertures at the base of the chelipeds are not involved in aerial respiration. In another freshwater crab, *Trichodactylus petropolitanus* (Trichodactylidae) the scaphognathites cease beating in air, although it was considered that air entered the branchial chamber by diffusion during aerial respiration in this animal[9].

In resting *Parathelphusa* the ventilatory movements are sporadic but after exercise become regular in frequency and depth, reaching a maximum rate of 20 cycles min^{-1} (each cycle represents one inspiration and expiration for each lung). During maximal ventilation the thoracic wall moves almost completely across the epibranchial chambers. It is estimated that at least 70–80% of the air in the lung is exchanged in each ventilatory cycle.

The oxygen extraction efficiency of the lung of *Parathelphusa* has not yet been measured. Ventilation of the gas exchange surface seems, however, to be more efficient than in *Birgus* or gecarcinids, where diffusion distances between the branchial tufts or gills are relatively long[4].

The muscular basis of ventilation is not yet known. It is possible that muscles homologous to the 'dorso–ventral muscles' described by Pearson[10] in *Cancer* are involved. These muscles run from the roof of the branchial chamber to the carapace. Contraction of these could effect inspiration while expiration in the contralateral branchial chamber would be simultaneously effected by hydraulic displacement of the haemolymph and viscera.

No similar ventilatory movements have been described in other crabs, although in *Birgus* carapace movements contribute in a minor way to air flow through the lungs[3]. Unlike a vertebrate, a crab's total volume is essentially fixed by its rigid exoskeleton. In this light the simultaneous inspiration and expiration in opposite chambers could be seen as a neat solution to the problem of lung ventilation.

Calcium couples flagellar reversal to photostimulation in *Chlamydomonas reinhardtii*

SEVERAL recent findings[1–3] suggest that the intracellular concentration of free calcium, $[Ca]_i$, has an important role in the regulation of ciliary and flagellar beating. For example, *Paramecium* extracted with Triton X-100 and reactivated with Mg^{2+} and ATP swim backwards when the Ca^{2+} concentration of the test medium, $[Ca]_o$, is raised above 10^{-6} M (ref. 1). Similarly, extracted cells of the typanosomid *Crithidia* show a reversal in wave propagation that is controlled by Ca ions. In studies on the intact flagellar apparatus isolated from a wall-less mutant of *Chlamydomonas reinhardtii*, the flagella have been shown to reverse direction of the effective stroke when external $[Ca]_o$ is raised above 10^{-6} M (ref. 3). Electrophysiological evidence indicates that, in *Paramecium*, reversal of ciliary beating is caused by Ca which enters the cell when the Ca permeability of the membrane is increased[4,5]. We have investigated whether Ca is involved in the phototactic response and more specifically whether this Ca influx is regulated by the cell membrane. Electrophysiological recording was impractical because of the small size of these cells (< 10 μm), and so the approach was to photograph the light-induced motor responses of cells swimming in solutions containing different concentrations of Ca or Ca-blocking agents. The results demonstrate that the reversed beating response of the flagella depends on Ca. Inhibition of the response by Ca-blocking agents supports the view that reversed beating response of the flagella is coupled to photostimulation by an influx of Ca ions.

Wall-less mutants of *C. reinhardtii* strain CW92 were grown axenically in liquid medium[6] at 25 °C with constant shaking under a 14-h light, 10-h dark cycle. Light was provided by Cool-white and Gro-lux fluorescent illumination at an intensity of 2.6 W m^{-2}. Response variability was minimal when cells were used between hours 67 and 77 after inoculation and between hours 3 and 6 of the light cycle.

Cells were centrifuged and resuspended twice in the experimental solution and were kept in the dark before transfer to a microscope slide. They were then examined by phase illumination under red light (Corning glass 2-62 sharp-cut filter, 600-750 nm) and left undisturbed while exposed continuously to the red light for 60–75 min before stimulation. Red illumination did not produce any overt behavioural response in these cells. The stimulus, a substitution of white light for the red light, was achieved by electromechanically replacing the red filter by a neutral density filter for approximately 280 ms. The red light had an energy before entering the microscope optics of ~ 80 W m^{-2} and the white stimulus light plus neutral density filter ~ 70 W m^{-2}. The temperature at the microscope stage was 20±1 °C. A fresh sample of cells was used for each experiment and each group of cells was stimulated only once.

The control solution contained 2 mM EGTA (ethylene glycol-*bis*-(β-aminoethylether)-*N*,*N*′-tetraacetic acid), 3 mM $CaCl_2$, 1 mM KCl, 0.1 mM $MgCl_2$, and 5 mM HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulphonic acid) at *p*H 7.1. Experimental solutions were identical except for the concentration of Ca or the addition of test substances as described below. $CaCl_2$ was added to the fixed concentration of EGTA in amounts yielding the desired concentration of free Ca for $[Ca]_o$ between 10^{-8} and 10^{-5} M (ref. 7). At higher concentrations the free Ca was regarded as the total Ca concentration minus the EGTA concentration.

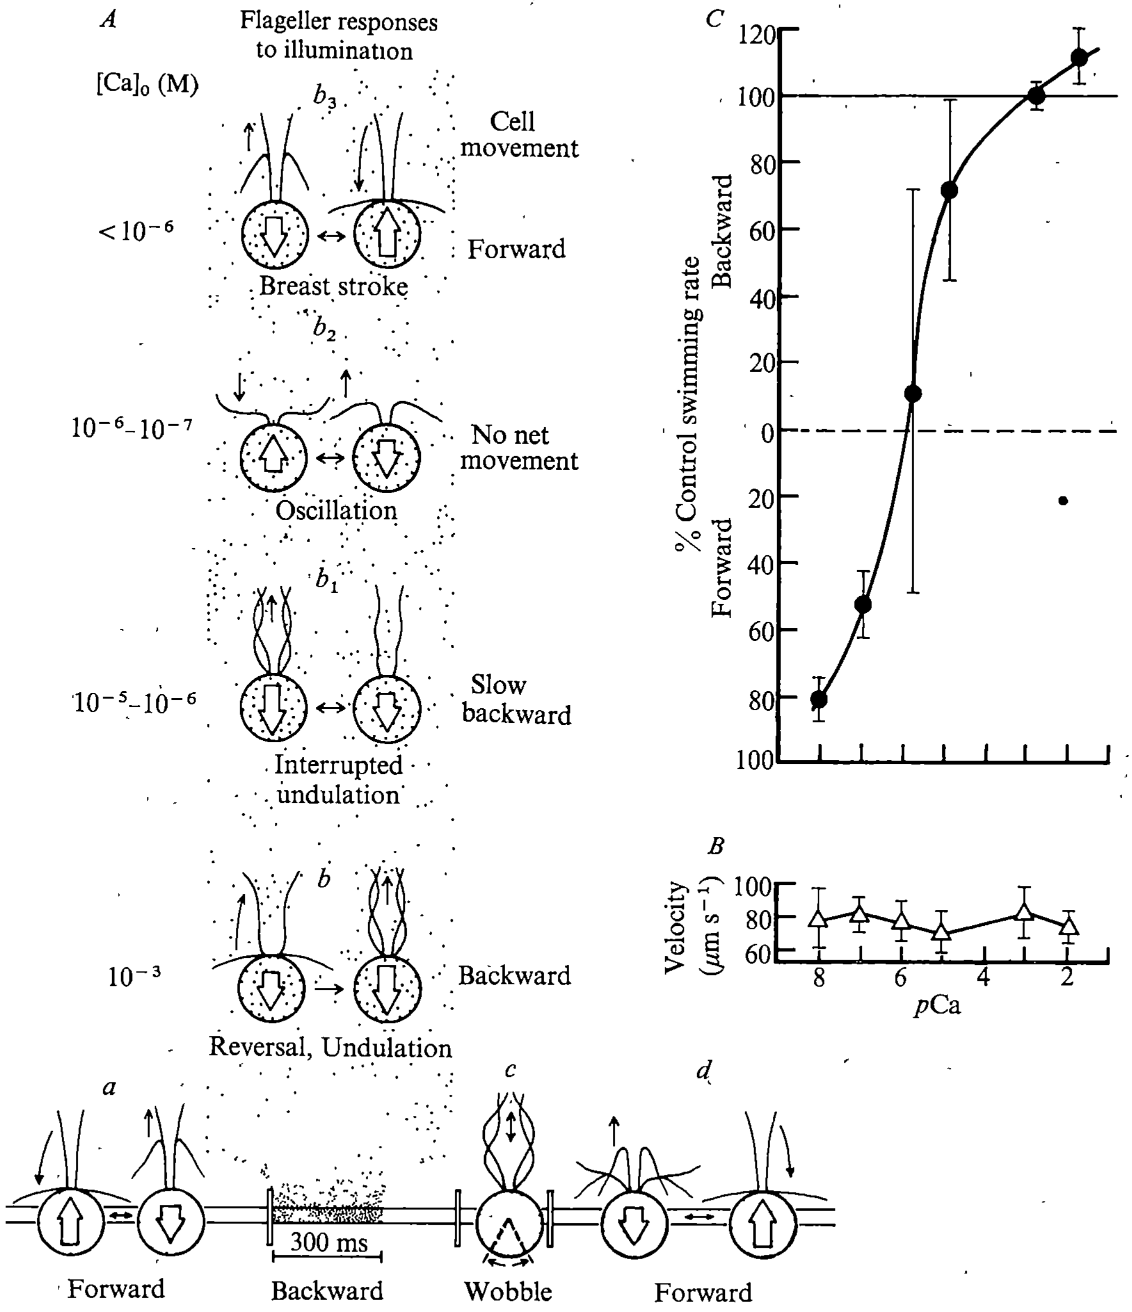
Analysis of cell and flagellar motion was carried out at 1,000× image magnification on Kodak 2496RAR film exposed in a LOCAM 16-mm camera at 200 frames per s. Frame-by-frame analysis of the recorded sequence was made on a Vanguard motion analyser, and representative flagellar configurations were traced by hand, and reproduced schematically in Fig. 1*a*. Backward swimming velocity is defined as the distance covered by the cell during an episode of backward swimming divided by the time elapsed during reversed locomotion. Forward swimming velocity was calculated from the distance covered by the cell in 150 ms. In those instances where forward locomotion was determined during a light stimulus the period of measurement began 20 ms after stimulus onset.

During forward swimming under red light the flagellar motion resembled a breaststroke[8,9] (Fig. 1*A*, bottom left, *a*). The power stroke consisted of the simultaneous movement of both flagella in a rather straight sweep bending only near the base. This stroke propelled the cell forward with the base of the flagella leading. The recovery stroke consisted of a wave propagating along the flagella from base to tip, which pushed the cell backwards slightly. A complete cycle of beating lasted about 20 ms. The time required for one complete cycle was determined to ±10 ms by measuring the time required for 5 beats to ± 10 ms.

Photostimulation in the control solution always produced a constant modification of flagellar movement and hence swimming behaviour (Fig. 1). The cell continued to swim forward for about one cycle (that is, 20 ms) after the onset of the stimulus and then stopped for about 20 ms. The power stroke then reversed (reversal in *b*, Fig. 1*A*), increased in frequency and caused the cell to back up. This reversed swimming was only seen in response to the photostimulation. Backward swimming continued for 200 ms after the stimulus. After 550±100 ms from the initiation of backward swimming the cell eventually slowed to a stop and for about 200 ms wobbled around its transverse axis (*c*, Fig. 1*A*). The cell moved about 14 μm in the reverse direction before resuming forward movement.

Changes in $[Ca]_0$ did not significantly affect forward swimming in the unstimulated cell (Fig. 1*B*) but markedly modified the light-induced responses (Fig. 1*A*, b_1–b_3). In the range of

Fig. 1 Dependence of *Chlamydomonas* photoresponse on $[Ca]_0$. *A*, Bottom, normal sequence (*a*, *b*, *c* and *d*) of flagellar behaviour and cell movement before, during and after a 300-ms light stimulus in control (that is 10^{-3} M Ca) solution. Durations of backward swimming and wobble are about 550 and 200 ms respectively. Reversal and termination of backward swimming latencies are 20 and 200 ms respectively. The response during light is shown on a larger scale in the expanded portion of the stippled area. Backward locomotion was progressively inhibited (b_1, b_2, b_3) by reduced $[Ca]_0$. *B*, Prestimulus velocity (μm s^{-1}) plotted against pCa_0. Bars give s.e.m. There was no significant difference in forward swimming velocity at $[Ca]_0$ between 10^{-8} and 10^{-2} M. *C*, Rate of swimming during photostimulation plotted against *p*Ca as percentage of prestimulus control swimming rate. Control swimming rates for both forward and backward locomotion represent rates measured at 10^{-3} M $[Ca]_0$. Backward locomotion was normalised to the forward control swimming rate. Bars give s.e.m. Backward locomotion is plotted above, and forward locomotion below the dashed line. Control swimming rate was restored after cells were transferred from a 10^{-8} M Ca solution to the control solution, 10^{-3} M.



10^{-5} to 10^{-6} M Ca there appeared interrupted undulations of the flagella (b_1, Fig. 1*A*). In addition, the velocity of reversed swimming became progressively slowed. At 10^{-6} M Ca the flagella of about 10% of the cells exhibited an oscillation in the focus plane which produced no net cell movemet (b_2, Fig. 1*A*). At concentrations less than 10^{-6} M Ca no reversed beating was observed in response to the stimulus (b_3, Fig. 1*A*) but there was a significant slowing of forward motion.

The rate of swimming in response to photostimulation is plotted against *p*Ca in Fig. 1*C*. The highest rate of backward swimming recorded was in 10^{-2} M Ca solution. At 10^{-6} M some cells swam backwards slowly while others swam forward. At less than Ca 10^{-6} M backward swimming could not be evoked with photostimulation; swimming continued in the forward direction during photostimulation with the highest observed rate at the lowest Ca concentration, 10^{-8} M. The effects of reduced Ca concentration on the response to photostimulation were reversed completely when cells were returned to the control solution.

The velocity of light-induced backward swimming was measured in the presence of agents known to block Ca influx in excitable membranes. Addition of 10^{-2} M Ba or 10^{-2} M Mg to the control solution resulted in a reduced velocity of backward swimming (Fig. 2). The effect was fully reversible. In addition, the organic Ca-blocking compound D-600 (α-isopropyl-α-α-[(*N*-methyl-*N*-homoveratryl)-γ-aminopropyl]-3,4,5-trimethoxyphenylacetonitrile)[10] inhibited backward swimming at 10^{-4} M or greater (Fig. 2). In contrast to Ba and Mg, however, the inhibition caused by this drug was irreversible. Procaine, a local anaesthetic which reversibly blocks membrane excitability[11] and is reported to be a competitor of Ca in the lobster axon[12], was found to block reversibly backward swimming at 10^{-2} M or greater (Fig. 2).

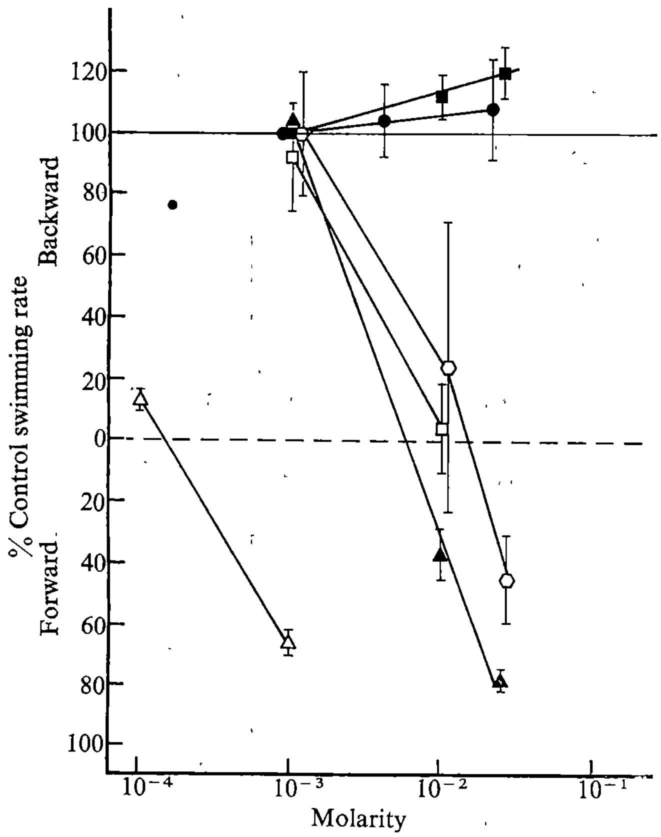


Fig. 2 Effect of several agents on backward swimming velocity in the presence of 10^{-3} M Ca. Percentage of swimming rate in control solution is plotted against concentration of each agent. Bars give s.e.m. Procaine concentrations were maintained at a constant 20 mosM with pentaerythritol. Ba, Mg and procaine inhibition was fully reversed by return to control solution. ●, Pentaerythritol; ▲, procaine; △, D-600; □, Ba^{2+}; ■, Ca^{2+}; hexagon, Mg^{2+}.

Lanthanum, Ni, Co and Mn ions, which generally block Ca currents in other membranes[13], have no effect on backward swimming at concentrations up to 1, 5, 50 and 80 mM respectively. At higher concentrations these cations were toxic. These agents also fail to block in *Paramecium* the Ca influx which mediates ciliary reversal[4,5,14,15].

The results presented here indicate that photostimulated flagellar reversal depends on extracellular Ca. The inhibition of the response by certain Ca-blocking agents such as D-600, procaine, Ba, and Mg, which are known to block Ca influx in other systems, suggests that photostimulation normally results in an influx of Ca through the cell membrane, producing a transient increase in $[Ca]_i$. The induction of reversed beating by Ca in the isolated basal body–flagellar apparatus[3] of *Chlamydomonas* supports this conclusion. Thus it seems that Ca^{2+} acts as the agent that couples flagellar responses to photostimulation in flagellate. This is reminiscent of the role of calcium in coupling ciliary reversal to membrane stimulation in the ciliated protozoa.

We thank Dr J. S. Hyams for providing the wall-less mutants of *C. reinhardtii* and Dr P. O'Lague for helpful discussion and critical reading of the manuscript. This work was supported by the NSF and USPHS.

Bioconversion of light energy into chemical energy through reduction with water of nitrate to ammonia

PHOTOSYNTHESIS is first and foremost a process for converting the radiant energy of sunlight into physiological chemical energy, that is, reducing power and high energy phosphate bonds[1]. Since, for historical and quantitative reasons, however, photosynthesis in a broad sense is commonly identified with the reduction of carbon dioxide to carbohydrate, the fact is often overlooked that photosynthetic organisms manufacture their most representative biomolecules—proteins and nucleic acids—not only from carbon dioxide, but also from other oxidised inorganic nutrients, especially nitrate, that, more or less directly, has to be reduced to ammonia by water before being incorporated into amino acids[2,3]. It was first thought[4] that the reduction of nitrate in green cells was a process far removed from the light reactions of photosynthesis and that carbohydrates were the *in vivo* source of reducing power for nitrate reduction, but it now seems that, at least in blue-green algae[5-7], the photosynthetic reduction of nitrate is even more direct than that of carbon dioxide, since it does not depend on adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide phosphate (NADPH), but only on reduced

Table 1 Photoreduction of nitrate to nitrite and ammonia coupled to oxygen evolution by particles of *Anacystis nidulans*

System	Nitrite formed (μmol)	Ammonia formed (μmol)	Oxygen evolved (μmol)
Complete	0.9	2.0	4.1
−Fd	0.7	1.6	3.5
$-NO_3^-$	0	0	0
+CMU	0	0.2	−0.4
Dark	0	0.2	−0.5

The complete system included in a final volume of 3 ml: 150 μmol Tricine–KOH buffer, *p*H 8.0; 30 μmol $MgCl_2$; 20 μmol KNO_3; 40 nmol *A. nidulans* ferredoxin (Fd); *A. nidulans* particles containing 0.63 mg chlorophyll. Where indicated, 0.3 μmol of 3-(*p*-chlorophenyl)-1-1-dimethylurea (CMU) was added. The reaction was carried out in air at 30 °C in Warburg vessels illuminated from below (20,000 lx) or kept in the dark. Reaction time 90 min. Other analytical methods as previously described[6]. Particles were prepared as follows: cells grown on nitrate in the light, as described previously[6], were collected in the exponential phase of growth, washed with 50 mM Tricine–KOH buffer, *p*H 8.0, 0.5 M sucrose, 10 mM $MgCl_2$, resuspended in the same buffer and broken with a precooled French press at 16,000–18,000 pound inch^{-2}. After digestion of the broken material with DNase and RNase for 10 min at 2 °C, the suspension was centrifuged at 3,000*g* for 10 min, the pellet discarded, and the supernatant centrifuged again at 40,000*g* for 20 min. The resulting sediment was washed once with the buffer, collected after centrifugation at 40,000*g* for 30 min, and finally resuspended in the buffer, to be used as a preparation of particles.

ferredoxin, the first electron acceptor from photosystem I. Also the enzymes for the reduction of nitrate to ammonia are retained tightly bound by the pigment-containing particles from these prokaryotes.

We report here the preparation of active and stable particles from the blue-green alga *Anacystis nidulans*, which, in the light and in aerobic conditions, can use water as the electron donor for the steady reduction of nitrate to nitrite and ammonia without the requirement of any exogenous enzyme system (Table 1).

During the past 15 yr, the assimilatory nitrate-reducing system, its regulation and its relation to photosynthesis have been studied, using a great variety of organisms[3,8,9]. Our results, as well as those from other groups[10], have firmly established that the nitrate-reducing enzyme system consists of only two metalloproteins—nitrate reductase and nitrite reductase—which catalyse in series the reduction of nitrate to nitrite and ammonia, through an unexpectedly short sequence of reactions

$$NO_3^- \xrightarrow{2e} NO_2^- \xrightarrow{6e} NH_4^+$$

Both enzymes are ferredoxin-dependent in the photosynthetic prokaryotes, but only nitrite reductase has such a dependence in the photosynthetic eukaryotes, a group which includes algae and higher plants. Nitrate reductase from eukaryotes is an NAD(P)H-dependent enzyme complex.

We have previously obtained isolated pigment-containing particles from *A. nidulans* that could carry out the ferredoxin-dependent photosynthetic reduction of nitrate and nitrite with the couple ascorbate–dichlorophenol indophenol as an artificial electron donor for photosystem I. The coupling of the process with the photolysis of water remained, however, an unsolved problem. There is also at the present time a direct interest in the photolysis of water by photosynthetic systems for fuel production, especially hydrogen gas, but these systems require auxiliary enzymes from other sources, and the removal of even traces of molecular oxygen is an absolute requisite[11]. Biological photofixation of nitrogen is also an anaerobic process but with high ATP requirements and its coupling with water photolysis will be even more difficult to accomplish (compare ref. 12).

In the system described here the electrons derived from the photolysis of water at photosystem II are transported to photosystem I and used for the stepwise reduction of nitrate to ammonia by the ferredoxin-dependent nitrate-reducing system, oxygen being evolved in stoichiometric amounts, according to the equations

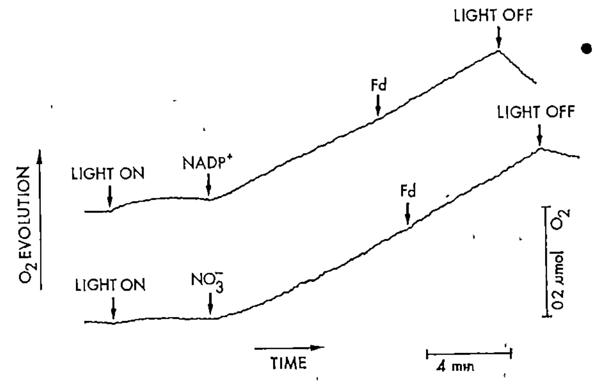

Fig. 1 Time course of oxygen evolution by *Anacystis nidulans* particles with either $NADP^+$ or NO_3^- as 'natural' Hill reagents. The reaction was carried out at 30 °C in the chamber of an oxygen electrode, either in the light (40,000 lx) or in the dark as indicated. Other experimental conditions were the same as in Table 1, except that a particulate preparation equivalent to 0.31 mg chlorophyll was used and that 4 μmol of $NADP^+$ were added as indicated in the corresponding system.

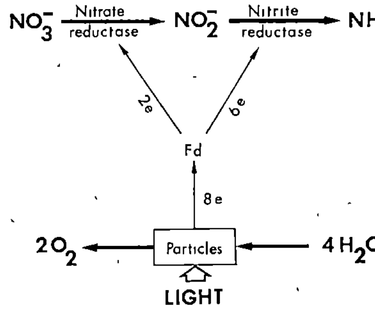
$$\begin{array}{r}
NO_3^- + H_2O \rightarrow NO_2^- + \tfrac{1}{2}O_2 + H_2O \\
NO_2^- + 3H_2O + 2H^+ \rightarrow NH_4^+ + \tfrac{3}{2}O_2 + 2H_2O \\
\hline
NO_3^- + 4H_2O + 2H^+ \rightarrow NH_4^+ + 2O_2 + 3H_2O
\end{array}$$

It can be seen in the table that the reaction depended on nitrate, was slightly stimulated by ferredoxin, and did not proceed in the dark or when an inhibitor of the photolysis of water was added. In the conditions of the experiment, the activity of the system was linear for at least 90 min. The small O_2 uptake in the presence of the inhibitor or in the dark might be related to the presence of an endogenous reducing material in the preparation.

Gerhardt and Trebst[13] have reported the ferredoxin-dependent non-cyclic photophosphorylation coupled to $NADP^+$ reduction and oxygen evolution by *A. nidulans* preparations obtained by vacuum drying. $NADP^+$ photoreduction by ferredoxin-NADP reductase and nitrate photoreduction by the ferredoxin-nitrate-reducing system are thus similar reactions. As Fig. 1 shows, our *A. nidulans* particles exhibited the same photosynthetic activities with either $NADP^+$ or nitrate as 'natural' Hill reagents[14]. Particles stored for 1 d at 2 °C remained fully active with respect to its nitrate-dependent, oxygen-evolving capacity, except for the ferredoxin requirement, that stimulated activity twofold after several hours and threefold after 24 h. Cell-free preparations from another blue-green alga—the N_2-fixer *Nostoc muscorum*—behave in a similar way (unpublished work from this laboratory).

Fig. 2 Diagrammatic representation of the ferredoxin-dependent photosynthetic reduction of nitrate to ammonia with water as the electron donor by blue-green algae particles. Fd, Ferredoxin.



In summary, subcellular preparations of blue-green algae can utilise the photochemically-generated reducing power coming from water for the direct reduction of nitrate to ammonia. The process can be considered as one of the most simple and relevant examples of photosynthesis. According to present knowledge, the ferredoxin-dependent photosynthetic reduction of nitrate and nitrite is shown in Fig. 2. Since 16 quanta of light are required to transfer 8 electrons from water to completely reduce one nitrate, the efficiency of the process (disregarding coupled photophosphorylation) is about 13%. Besides its biochemical and chemical interest, ammonia is an excellent fuel and can also be regarded as a portable source of hydrogen[15].

Cell differentiation without morphogenesis in *Dictyostelium discoideum*

To understand pattern formation in an organism one needs to know what factors control the differentiation of each cell type and what elements are responsible for the spatial arrangement of these cell types. In the cellular slime mould *Dictyostelium discoideum*, the problem is relatively simple since the mature fruiting body consists of two basic cell types—stalk cells and spores. The stalk cells of the mature fruiting body are derived from the anterior cells of the multicellular masses formed by aggregation, whereas the spores are derived from the posterior cells[1]. Cells that are plated at a density too low for aggregation, or are allowed to aggregate under water do not normally differentiate into stalk or spore cells. In many of our experiments we have made use of the fact that cells plated on agar at any density fail to undergo development beyond the stage of aggregation if they are covered by a thin layer of Cellophane. In this paper we present observations on cell differentiation which derive from the original report of Bonner[2] of stalk-cell induction by cyclic AMP in isolated cells. We have found that stalk-cell induction by cyclic AMP is markedly dependent on cell density, and present evidence for the involvement of a low molecular weight diffusible factor in this process. We also describe the isolation of a mutant which gives rise to spore cells under cellophane.

Bonner[2] reported that a proportion of amoebae of strain NC4 developed into large vacuolated stalk-like cells when plated on agar containing 1 mM cyclic AMP at cell densities that were too low to allow aggregation in controls without cyclic AMP. This observation was extended by Chia[3] who showed that when cells of P4 (a 'stalky' mutant of strain NC4) were plated at high density on a Cellophane support over a reservoir of 1 mM cyclic AMP, they collected into mounds in which all the cells differentiated into stalk cells. Cells of the parent strain NC4 collected into similar mounds, but only a proportion of them differentiated into stalk cells. In conditions similar to those of Bonner[2] (described in Fig. 1) we found that strains NC4, NC4/P4 and NC4/Ax-2 differentiate at a relatively low frequency, whereas strain V-12 M2 formed almost 100% stalk cells. Thus when cells were spread at a denstiy of 10^5 cells cm^{-2} on agar containing 5 mM cyclic AMP, the stalk-cell induction frequencies in strains V-12 M2, NC4, P4 and Ax-2 were 93, 4, 10 and 2%, respectively. At a density of 10^4 cells cm^{-2} and on 1 mM cyclic AMP, V-12 M2 produced 24% stalk cells, whereas the other three strains did not produce any. No stalk cells were observed in controls in the absence of cyclic AMP at 10^4 cells cm^{-2} or in controls at 10^5 cells cm^{-2} where the cells were overlain with Cellophane to prevent fruiting.

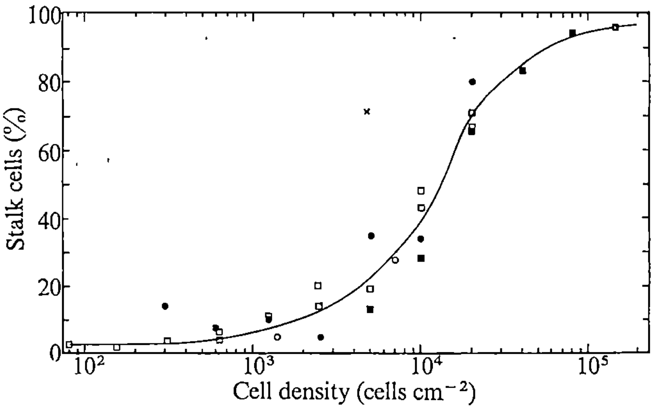

Fig. 1 Effect of cell density on stalk-cell induction by cyclic AMP. Cells were grown for 18–24 h with *K. aerogenes* on SM agar at 22 °C. They were collected and washed three times in 1% Bonner's salts and then spread at various cell densities on non-nutrient stalk-cell agar plates with or without cyclic AMP. The stalk-cell plates contained 1% Difco Bacto agar in 1% Bonner's salts, 100 μg ml^{-1} streptomycin sulphate, 25 μg ml^{-1} Calcofluor White 'New M2R' (Cyanamid, UK) with or without cyclic AMP; a total volume of 2.0 ml in a 5-cm plastic Petri dish. The plates were incubated in moist, dark conditions for 2–3 d and then examined by phase and fluorescence microscopy. Independent experiments are shown by different symbols. Cyclic AMP concentration was 1 mM in all experiments except one at the highest cell densities (■) when it was increased to 5 mM to prevent fruiting and ensure efficient-stalk cell induction. All control plates had less than one stalk-cell in 200 cells examined.

We have examined stalk-cell induction in strain V-12 M2 over a range of cell densities from 80 to 10^5 cells cm^{-2} (a density at which aggregation occurs on the control plates but not on those containing 1–5 mM cyclic AMP). The results are shown in Fig. 1. At cell densities greater than 4×10^4 cells cm^{-2}, almost all of the initially vegetative amoebae were transformed in 2–3 d into stalk-like cells, as judged by their morphology under phase-contrast and in electron micrographs, as well as by their staining with the cellulose-specific indicator calcofluor[4]. The frequency of stalk-cell induction decreased quite rapidly as cell density was reduced, reaching a basal level of approximately 3% below 500 cells cm^{-2}. At high cell densities, a considerable proportion of the initially separate cells were present in small clumps after 2–3 d incubation and this proportion declined as cell density was lowered.

At cell densities between 5×10^3 and 2×10^4 cells cm^{-2}, 70–100% of the cells in small clumps became stalk cells, whereas only 30% of the single cells on the same plates were induced. This latter figure is in turn much higher than the value of 3% observed at very low density (Fig. 1). It therefore seems that cyclic AMP can induce differentiation of isolated amoebae

Table 1 Enhancement of stalk-cell differentiation in isolated cells by a diffusible factor from cells differentiating at high density

Tester cell density (no. of determinations)	% Stalk-cell differentiation			
	Tester cells alone		Tester cells plus high density helper cells	
	Control	Cyclic AMP	Control	Cyclic AMP
10^3 cells cm^{-2} (3)	1.3	4.3	0	80.0
2×10^3 cells cm^{-2} (2)	0	1.3	0	39.6
5×10^3 cells cm^{-2} (1)	0	4.5	0	79.6

Cells were prepared and spread on 1% agar containing 1% Bonner's salts with or without 5 mM cyclic AMP as described in Fig. 1. The first layer of cells was overlaid with Cellophane and, where appropriate, a second layer of cells. In some experiments buffer (5 mM MES, *p*H 6.0) was included in the agar to exclude the possibility of a *p*H artefact. This buffer has no effect on the induction process. After 2–3 d, a coverslip was placed on the upper layer of cells and the dishes examined by phase contrast microscopy. Stalk cells were identified by their vacuolated morphology, the remaining cells appearing amoeboid. Induction in the high density population was essentially 100% in all cases. Cellophane 325P (British Cellophane) was prepared by boiling in 1 mM EDTA for 15 min followed by extensive washing in distilled water. It was impermeable to Dextran blue 2000 (molecular weight 2×10^6) and to inulin (molecular weight ~ 5,000).

into stalk cells, but that the efficiency of conversion is greatly enhanced by some kind of cell interaction.

The density dependence of stalk-cell induction and the enhanced conversion of single cells at high density could be interpreted in terms of a diffusible inducer or of a process of contact-dependent induction. To distinguish between these possibilities, we asked whether cells undergoing stalk cell differentiation at high density could enhance the frequency of stalk-cell formation in a low density population separated from them by a Cellophane membrane. Similar tests of synergism have been used by other workers[5,6]. The results are shown in Table 1. The low density populations alone had an induction frequency of 0–5%, whereas the same cells plated over a dense layer of 'helper' cells gave a frequency of 40–80%. In similar experiments we have found that V-12 M2 'helper' cells also increase the efficiency of stalk-cell induction in strain NC4 and its derivatives. These results suggest that cells undergoing stalk-cell differentiation at high density secrete a dialysable factor which is capable of enhancing cyclic AMP-induced differentiation in isolated cells. It is still possible that actual cell contact is required for the synthesis of this factor by the 'helper' cells.

We have isolated a number of developmentally defective mutants of V–12 M2 after nitrosoguanidine or ethylmethanesulphonate mutagenesis and have screened them for stalk-cell inducibility by cyclic AMP. Only two out of seven totally aggregation-defective mutants were inducible. On the other hand, 14 out of 15 mutants which aggregated but either failed to develop further, or gave aberrant or delayed fruits, were inducible by cyclic AMP. This result suggests that certain events involved in the attainment of aggregation competence are essential for stalk-cell induction.

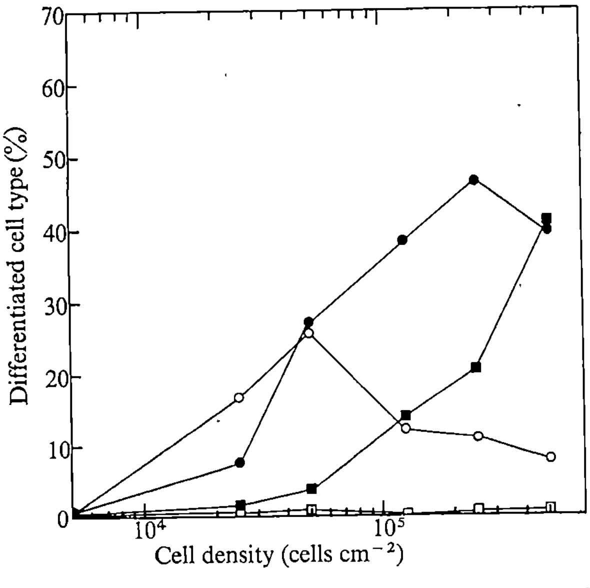

Fig. 2 Formation of stalk and spore cells by mutant *sci-1* under Cellophane. *Sci-1* cells were collected from growth plates in KK_2 buffer (16.5 mM KH_2PO_4, 3.8 mM K_2HPO_4, 2 mM $MgSO_4$, *p*H ~ 6.2) with 60 mM KCl added and pelleted at 200*g* for 5 min. After three further washes in KK_2 and one in 1% Bonner's salts solution, the cells were spread at the stated densities on 2 ml 1.5% agar (Oxoid L28) containing 1% Bonner's salts, 250 μg ml^{-1} streptomycin with or without 5 mM cyclic AMP, in a 5-cm diameter Petri dish. Cellophane was then placed over the cells and after 2–4 d incubation at 22 °C, stalk and spore cells were scored microscopically. At least 200 cells were scored on each plate and the results given are the average of five separate experiments. Two of these experiments were carried out on the original isolate of the mutant and three on clone 5 derived from it. ■, Spore+cyclic AMP; ●, stalk+cyclic AMP; □, spore, no cyclic AMP; ○, stalk, no cyclic AMP.

Table 2 Enhancement of differentiation of *sci-1* at low density by high density wild-type or *sci-1* cells

Cell density and genotype		% Differentiated cell type observed			
Above Cellophane	Below Cellophane	Above Cellophane		Below Cellophane	
		Stalk	Spore	Stalk	Spore
5×10^3 cm^{-2} mutant	None	4.3	0.4	—	—
5×10^3 cm^{-2} mutant	2.5×10^5 cm^{-2} mutant	43.3	8.1	39.5	12.6
5×10^3 cm^{-2} mutant	2.5×10^5 cm^{-2} wild type	27.0	8.9	79.3	0

Cells of the mutant (*sci-1*, clone 5) and wild type were collected as described in Fig. 2. Cells of either type were plated at high density directly on to agar (2 ml 1.5% agar containing 1% Bonner's salt solution, 5 mM cyclic AMP, 250 μg ml^{-1} streptomycin in a 5-cm diameter dish). Cellophane (325P) was placed on top and a low density of *sci-1* cells spread on it. In control plates the high density cells were omitted. After 2–4 d at 22 °C a coverslip was placed on the upper layer of cells and the cells scored above and below the Cellophane. Results are means of three experiments.

Because stalk cells are non-viable[7] and our induction procedure is efficient, we have been able to use the cyclic AMP induction procedure to enrich for resistant mutants in a mutagen-treated population. These experiments were carried out using an acriflavine-resistant mutant of V-12 M2 which gives reasonably compact plaques when plated with *Klebsiella aerogenes* on medium containing acriflavine. The majority of the non-inducible mutants isolated by this procedure show aberrant development, most being aggregation defective. During the screening of colonies surviving the selection procedure, we encountered one unusual mutant (*sci-1*) in which cyclic AMP induced the formation of spores—identified by their morphology and survival after exposure to heat[8] or detergent (R. R. Kay, unpublished and ref.9). Figure 2 shows the pattern of differentiation of cells of *sci-1* at various densities under Cellophane in the presence and absence of cyclic AMP. In the presence of cyclic AMP the mutant formed both stalk cells and spores. The formation of both was density dependent; however, stalk-cell differentiation was relatively more efficient at low density and was reduced at high density. In the absence of cyclic AMP, few spores were produced at any density, whereas the frequency of stalk-cell differentiation reached a maximum at 5×10^4 cells cm^{-2} and then declined. The mutant cells incubated at low density in the presence of 5 mM cyclic AMP could be induced to differentiate into both stalk and spore cells by a high density of either *sci-1* or wild-type V-12 M2 cells (Table 2).

In normal developmental conditions the mutant produces pyramidal fruits, sometimes with a bulbous tip, composed of jumbled patches of stalk and spore cells. Similarities between the fruit of *sci-1* and the mutant *Fr17* previously isolated by Sonnenborn *et al.*[10,11] prompted us to examine the behaviour of *Fr17* under Cellophane. Vegetative cells of *Fr17* at low density (5×10^3 cells cm^{-2}) placed under Cellophane produced less than 1% stalk or spore cells, with or without cyclic AMP. At high cell densities (5×10^5 cells cm^{-2}), however, it produced 60–70% spores and 1–10% stalk cells in the presence or absence of cyclic AMP.

We are at present attempting to purify the putative factor(s) that enhances stalk-cell induction by cyclic AMP. The factor seems to be stable since cell-free medium collected after stalk-cell induction in dense cells increases the yield of stalk cells in low density populations. Knowledge of the identity of the factor(s) should be helpful in elucidating its role (if any) in normal development, and will also enable us to test whether the same factor is implicated in the density-dependent differentiation of stalk cells and spores in mutants *sci-1* and *Fr17*. In any event the use of a Cellophane overlay to examine cell differentiation in the absence of normal morphogenesis should facilitate further analysis of the interplay of elements responsible for pattern formation in *D. discoideum*.

Somatic hybridisation of *Penicillium roquefortii with P. chrysogenum* after protoplast fusion

FUSION of fungal protoplasts after treatment with polyethylene glycol (PEG) has been described as a new technique for intraspecific heterokaryon formation at high frequency[1-3]. We now report the formation of interspecific somatic hybrids between *Penicillium roquefortii* and *P. chrysogenum* by PEG-induced fusion of their protoplasts.

Stable auxotrophic mutants of *P. roquefortii* (University of Nottingham Collection) and *P. chrysogenum* Wis. 49-2105 were obtained after treatment with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine[4]. Symbols designating the requirements of the mutant strains and the mutant spore colour are as follows: *met/cys/glu/val* (methionine or cysteine or glutamine or valine); *met* (methionine); *trp* (tryptophan); *lys* (lysine); *arg* (arginine); *leu* (leucine); *lys pro/arg* (lysine and proline or lysine and arginine); *leu met/cys* (leucine and methionine or leucine and cysteine); *whi* (white spore colour); *ylo* (yellow spore colour). Strains were maintained and allowed to sporulate on a complete medium (CM)[5]. Mycelium for protoplast formation was grown in a production medium (PM), consisting of inorganic minimal medium (MM)[5] supplemented with 0.2% Difco yeast extract and the requirements of the auxotrophs. Protoplasts were produced as described previously[5] and fusion was carried out as for intraspecific protoplast fusion[1,3]. Suitable dilutions were plated on to hypertonic MM to select fused protoplasts of nutritionally complementary strains. Surviving protoplasts were counted on hypertonic PM.

After PEG treatment of a mixture of complementing *P. roquefortii* and *P. chrysogenum* protoplasts, small prototrophic colonies developed on MM. No growth was observed on MM when protoplasts of the two strains were mixed without PEG or when they were treated separately with PEG and then mixed. Spores could not be fused and did not germinate on MM in any of the conditions tried. These results indicated that the prototrophic colonies arose from balanced fused protoplasts of *P. roquefortii* and *P. chrysogenum* and that they were not the result of back mutation or cross feeding between unfused protoplasts. Fusion frequency was 0.03–3.4% (Table 1). These yields were similar to those obtained for PEG-induced intraspecific protoplast fusion[1,3]. Pure lines of interspecific hybrids were established by repeated cloning of single protoplasts produced from mycelium grown in MM shake cultures inoculated with prototrophic mycelial fragments. After plating on MM, single protoplasts reverted to prototrophic colonies and this procedure could be repeated indefinitely.

The colonies of the interspecific hybrids were morphologically different from the parental strains and they could be classified into three main types (Fig. 1). On MM, type 1 colonies were slowly growing with limited hyphal branching and failed to sporulate. On CM, on PM or on MM supplemented with the requirements of either one of the parental strains, they grew faster and produced parental auxotrophic *P. roquefortii* spores. *P. chrysogenum* spores, however, were never observed. Type 1 colonies predominated in the first culture after fusion treatment and when protoplasts were prepared from 6-d-old MM cultures of type 1 mycelial fragments. On the other hand, when type 1 mycelium was incubated for 10–12 d, more protoplasts developed into type 2 colonies, consisting of a loosely meshed network of broadly spreading hyphae. Like type 1 colonies, they did not sporulate on MM, and they produced only *P. roquefortii* auxotrophic spores on CM or PM. Protoplasts from type 2 mycelium reverted to type 2 colonies, irrespective of the age

Table 1 Percentage of fusion between protoplasts of *P. roquefortii* and *P. chrysogenum* complementing auxotrophs

P. roquefortii auxotrophs*	*P. chrysogenum* auxotrophs*				
	lys pro/arg whi	*leu met/cys ylo*	*lys*	*leu*	*arg*

Protoplasts, produced by treatment (27 °C, 4 h) of 20-h-old mycelium with *Oxyporus* cellulase (5 mg ml^{-1}) and Strepzyme 12,705 (10 mg ml^{-1}) in 0.8 M $MgSO_4$ (for *P. roquefortii*) or 0.6 M NaCl (for *P. chrysogenum*) were separated from mycelial debris by filtration through a sintered glass filter (porosity 1). Fusion was achieved by mixing washed protoplasts (10^5 of each auxotroph), treating them (30 °C, 10 min) with 1 ml of 30% (w/v) PEG molecular weight 6,000 in 0.01 M $CaCl_2$ and 0.05 M glycine adjusted to *p*H 8.0 with NaOH, and eliminating PEG by three washes in 0.8 M NaCl. Protoplasts were plated on to MM and PM to determine percentage of fusion.

*About 10% of the protoplasts regenerated on PM after fusion treatment[3].

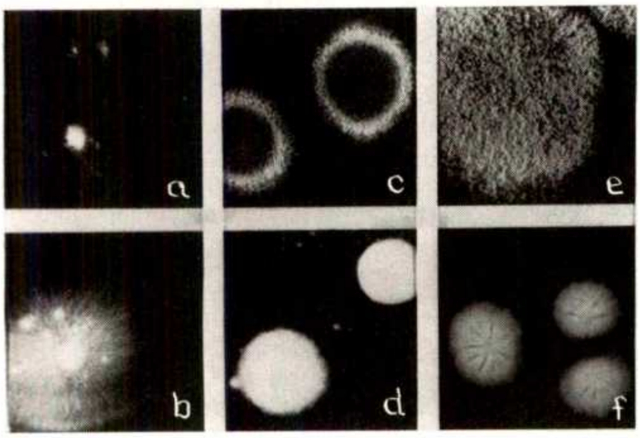

Fig. 1 Different types of colonies after reversion of protoplasts of *P. roquefortii met/cys/glu/val*, *P. chrysogenum lys pro/arg whi* and their interspecific somatic hybrids. *a*, Type 1 colonies on MM; *b*, type 2 colonies on MM; *c*, sporulating type 1 colonies on MM supplemented with methionine; *d*, type 3 colonies sporulating on MM; *e*, parental *P. roquefortii met/cys/glu/val* on MM supplemented with methionine; *f*, parental *P. chrysogenum lys pro/arg whi* on MM supplemented with lysine and proline.

of the mycelium. Colonies with compact mycelium and conidiophores branched similarly to *P. chrysogenum* were designated type 3. They appeared, usually less than 0.1% of the total, among type 1 and type 2 colonies after reversion of protoplasts from type 1 or type 2 mycelium. Type 3 colonies sporulated even on MM and released greenish-white prototrophic spores with a larger diameter than those of the parental strains (Table 2). Single spore isolates and protoplasts again developed into type 3 colonies. Occasionally, the latter colonies showed sectors of *P. roquefortii* spores.

The ability of type 1 and type 2 mycelia to release parental *P. roquefortii* spores showed that *P. roquefortii* nuclei were present in the interspecific mycelium. On the other hand, the prototrophy as well as the ability of type 1 and type 2 mycelium to revert to *P. chrysogenum*-like type 3 colonies indicated that at least part of the *P. chrysogenum* genome was present. Further evidence for this was obtained from studies of penicillin production by the interspecific progeny (Table 2). When grown in a rich fermentation medium[6] or in the medium of Jarvis and Johnson[7] (JJ), mycelium of all colony types produced antibiotic substances, which were inhibitory to *Sarcina lutea* ATCC 9341 and to a penicillin-sensitive *Staphylococcus aureus* ATCC 6558•P, but not to a penicillin-resistant *Staphylococcus*. The antibiotic activity disappeared on treatment with penicillinase. Paper chromatography[8] and gas–liquid chromatography[9] showed that the antibiotics were a mixture of benzyl penicillin, *n*-amyl penicillin and 2-pentenyl penicillin. When grown in a suitable medium[6], the parental *P. chrysogenum lys pro/arg whi* produced a similar mixture of penicillins. But growth of this strain, either alone or cocultivated with *P. roquefortii*, was completely inhibited by the ammonium lactate and ammonium acetate in JJ medium. In contrast, the interspecific hybrids and *P. roquefortii* grew well in JJ medium, but neither the *P. roquefortii* culture filtrates nor mycelial extracts contained any antibiotic substance when assayed against *S. lutea* or *St. aureus*. Thus it seems unlikely that the penicillins in the cultures of the interspecific mycelium were produced by segregated parental *P. chrysogenum*. Moreover, the latter was never re-isolated.

Although conclusive evidence is lacking, several observations indicated that mycelium from type 1 and type 2 colonies was heterokaryotic, whereas type 3 mycelium might be diploid. Type 1 and type 2 colonies were prototrophic and produced penicillins, but released parental *P. roquefortii* spores. Moreover, growth and sporulation were stimulated by addition of the amino acids required by either of the parental strains (Table 2), indicating that the nuclei of both complementing strains were still present. Type 3 colonies produced penicillins and formed prototrophic spores with a larger diameter. Furthermore, they sometimes showed sectors of haploid *P. roquefortii* segregants. Those characteristics obviously suggest diploidy. It is, however, still unclear why only *P. roquefortii* and not *P. chrysogenum* could be re-isolated. *P. roquefortii* might be dominant over *P. chrysogenum* for certain alleles and could have repressed the formation of *P. chrysogenum* spores. On the other hand, it cannot be excluded that *P. chrysogenum* should have lost chromosomal material. Loss of chromosomes is a common phenomenon after somatic fusion of mammalian cells[10,11].

The present studies demonstrate that somatic hybrids of related species of *Penicillium* can be produced by PEG-induced fusion of their protoplasts. Whether it will be possible to obtain viable hybrids of less related species is under investigation.

We thank P. Adriaens and B. Meesschaert for chromatographic determination, Dr J. F. Peberdy for discussion and

Molecular imaging of dislocations in 16 chlorocopper phthalocyanine

DISLOCATIONS in molecular crystals are well known, but have been studied on the microscale chiefly with a view to establishing their role in phase changes[1] or topotactic transformations[2]. Here, the positions of individual molecules can be identified, and, in so far as 16 chlorocopper phthalocyanine is a typical molecular crystal, the results are important for concepts of dislocations and intercrystalline boundaries in such crystals.

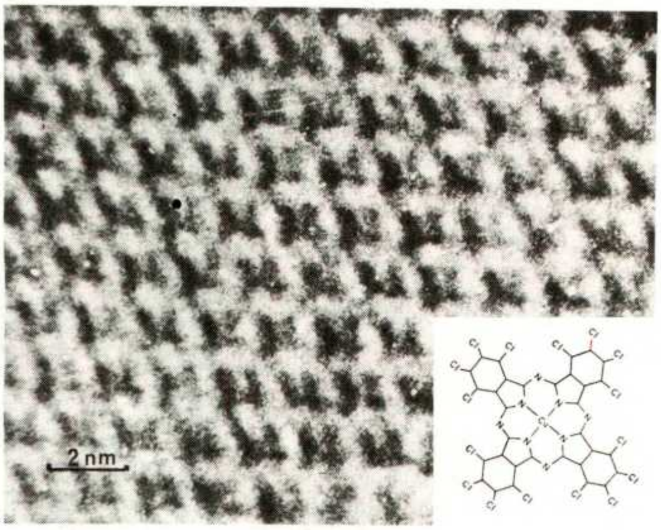

Fig. 1 Perfect crystal of 16 chlorocopper phthalocyanine lying on (001) face.

Figure 1 shows an area of a perfect crystal and illustrates some facets of the electron microscopy used for imaging. First, the crystalline film was prepared epitaxially on KCl at 200 °C at a maximum thickness < 20 nm. The film was then supported on a dimpled micromesh specimen grid—dimpled to provide a varied orientation of the specimen film, rather than using a tilting stage, with its commensurately poorer resolution. The film was lying on the (001) face and as Fig. 2 shows, the specimen had to be tilted, so that the columns of molecules are parallel to the electron beam[3]. This material, like all molecular crystals, is very sensitive to electron radiation damage, so exposure to the electron beam must be minimised. Ilford Industrial G X-ray film was used to record the image, with a very short exposure time.

With this specimen thickness and for this material in this orientation, dynamical imaging effects should be absent and computed images[4,5], allowing for instabilities of lens constants and for partial coherence, showed that 80 nm was the optimum defocus position. Also, for this size of molecule rapid oscillations of the phase contrast transfer functions do not occur within 20 nm of the optimum defocus position, so there should not be significant contrast change within the thickness of the film. In the light of present knowledge of electron optical imaging, therefore, we believe that the images represent the structure of the specimen.

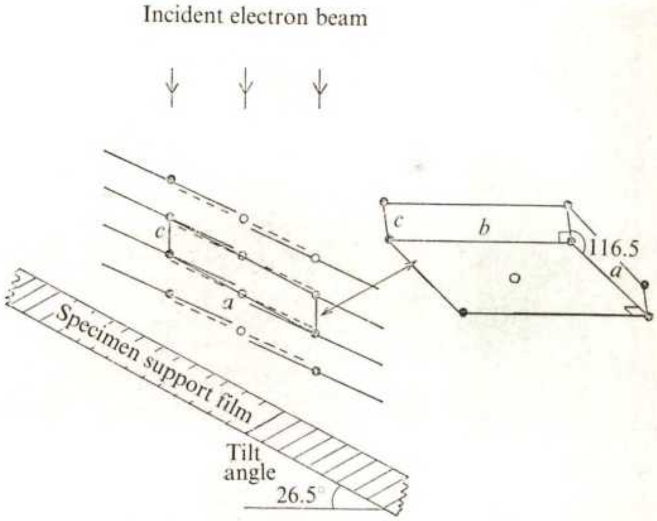

Fig. 2 Projection of molecular stacking along *b* axis showing required specimen tilt for molecular imaging, and geometry of unit cell. (Space group $C2/c$) ●, Copper atom at corners; ○, copper atom at face centre.

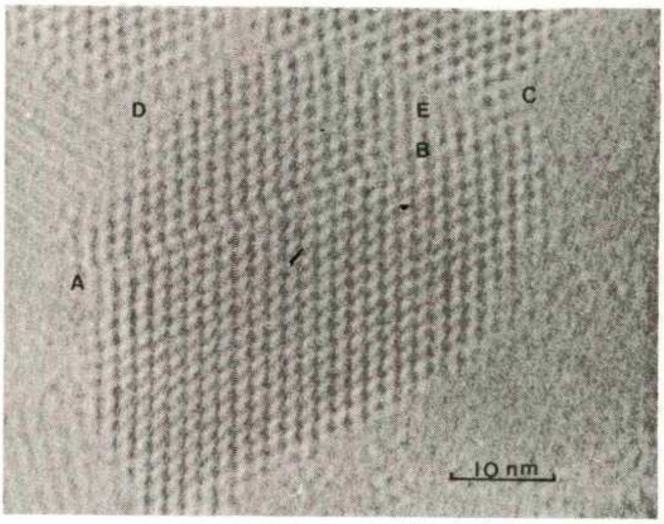
Many dislocations were observed, but since the crystallite size was small (< 2,000 nm^2) the internal dislocation density was small and was not statistically significant compared with the extent of grain boundaries. Dislocations of all types were present and examples of each will be discussed.

Figure 3 shows a dislocation A–B which, at first sight, suggests a tilt or twin system, but since the contrast on either side of A–B is similar, the vertical orientation of the columns of molecules on either side must be similar; a screw dislocation of vector $\frac{b}{2}\langle 110\rangle$ would explain the image. There is a contrast change at B that could be ascribed tentatively to the interaction of this screw dislocation with the strain field of a mainly edge

Fig. 3 Imperfect region of crystal showing line dislocations and boundaries.



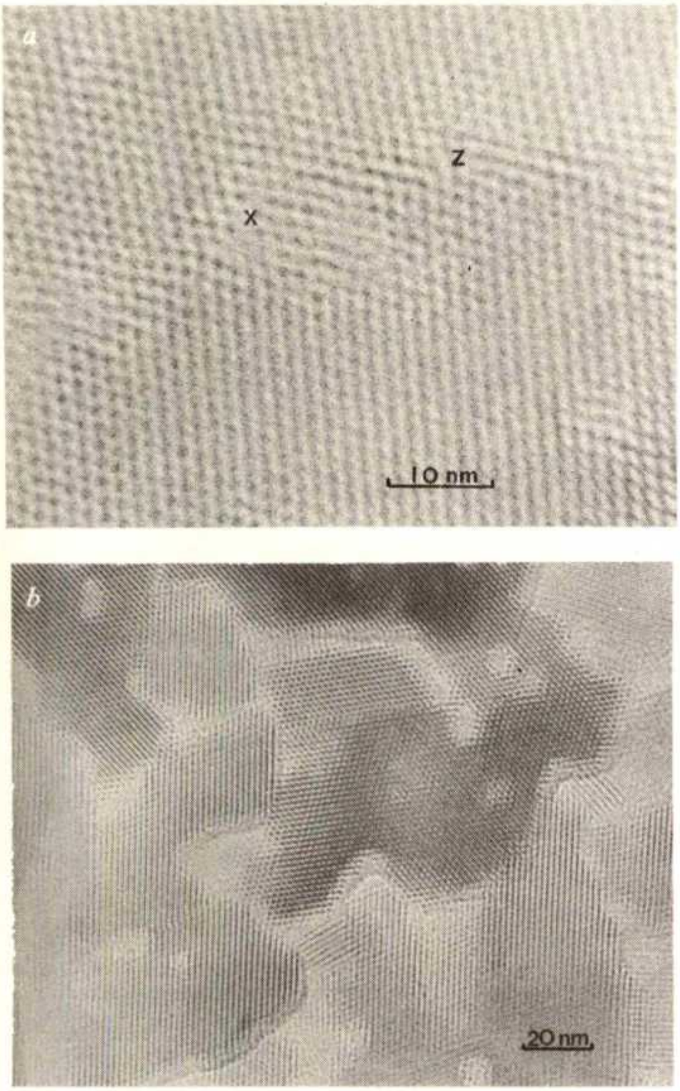


Fig. 4 *a*, Imperfect region of crystal showing column vacancies and other dislocations. *b*, Crystal boundaries showing distortion of peripheral molecular stacking, to reduce the boundary strain energy.

dislocation situated at C, but the presence of the boundary, DE, prevents more accurate identification. DE may be described as a grain boundary in spite of the close geometric relationship across the boundary which is a feature of these crystals.

Figure 4*a* shows a region of distortion with an apparent vacancy at X. This corresponds to the absence of a column of molecules, since even half a column would still have significant contrast in spite of its different defocus position. To the right of the vacancy, there is some tilting of the crystal as shown by the absence of images of discrete molecular columns, but a clear boundary between the two regions of the crystal cannot be determined. Individual dislocations—for example, in region Z—can be distinguished, but they are notable for both their small cores and small strain fields, although the dislocations may be affected by the presence of the boundary. Similar accommodation of distortion is also shown for the grain boundaries in Fig. 4*b*.

It is this lack of definition of boundaries and high distortion that is unexpected in these micrographs. We had anticipated that crystallites would be isolated entities, and that there would be a well defined strain field around each dislocation and internal boundary. In fact, neither is evident; the grain boundaries are not clearly defined, and there has been considerable molecular mobility at boundaries to reduce strain. The accommodation of considerable distortion in these crystals therefore suggests that molecular orientation is not sharply defined in these molecules and their effective radii can vary considerably. This is important for the concept of minimum-energy boundaries and implies that polycrystalline aggregates have a more intimate relationship than has hitherto been thought.

We are grateful to the SRC for provision of equipment, and also a maintenance grant (to Y.M.).

Models for the bacterial iron-transport chelate enterochelin

MICROBIAL iron-transport compounds, or siderochromes are of two general structural types, the phenolates and the hydroxamates[1,2]. X-ray studies of several of the latter, for example, ferrichrome A (ref. 3), ferrioxamine E (ref. 4) and mycobactin P (ref. 5), establish the anion of hydroxamic acid ($-N(O^-)CO-$) as the dominant metal-binding moiety, with discrete, neutral $[FeO_6]$ (refs 3 and 4) or $[FeO_5N]$ (ref. 5) units being involved. No similar structural data are at present available, however, for any member of the phenolate class and there is some ambiguity about the metal-binding sites. This is demonstrated for the most widely studied member of the group, enterochelin (or enterobactin), in Fig. 1. Both modes of attachment have parallels in the well known colour reactions of iron(III) with phenols, polyphenols and catechols and in the strong coordination of deprotonated amide nitrogen in simple peptide complexes of the transition elements[7]. Furthermore, molecular models (Drieding or CPK) of iron (III) enterochelin can readily be constructed with either bonding combination. Here we report our studies of two catechol (1,2-dihydroxybenzene) complexes containing the coordination type given by Fig. 1*a* and compare some of their properties with those of iron(III)-enterochelin (part of this work was presented in ref. 8).

Following Selles[9], two complexes were crystallised from ethanol or ethanol–water mixtures containing ferric acetate, catechol and piperidine. Conditions of low base yielded deep purple crystals, whereas excess piperidine resulted in burgundy-red crystals. X-ray data for both compounds were recorded with graphite-monochromated CuKα radiation ($\bar{\lambda} = 1.5418$ Å), using a Picker-FACS I four-circle diffractometer and a θ–2θ scan technique.

Crystals of the purple racemic piperidinium μ-acetato-di-μ-1,2-benzenediolato-*bis*-1,2-benzenediolatoferrate(III), $(C_5H_{12}N)_3[(CH_3COO)\{Fe(C_6H_4O_2)_2\}_2]$ are tetragonal, space group $P\bar{4}$, with $a = b = 27.593(3)$, $c = 12.234(2)$ Å, $Z = 8$, $D_m = 1.23$, $D_c = 1.227$ g cm^{-3}. The crystals showed a rapid decrease in reflection intensity with increasing scattering angle and only 2,467 unique reflections of some 16,000 collected had intensities greater than $3\sigma(I)$. The structure was solved by Patterson and Fourier techniques, and refined by large-block least-squares methods, giving $R = 0.092$. At the present stage of refinement, hydrogen atoms have not been included in the scattering model and although the correctness of the structure is not in doubt, the precision of the final result will be limited by the unfavourable data–parameter ratio and by the apparent disordering of one piperidinium cation. Two crystallographically distinct dimeric units of similar structure are present in the asymmetric unit together with piperidinium cations. As Fig. 2*a* shows, the two $[FeO_6]$ octahedra share a common edge using oxygens of two catechol dianions and adjacent apical coordination sites are bridged by an acetate ion. Each octahedron contains one bidentate catechol moiety which is not involved in bridging the metal atoms. The Fe–O bond lengths are in the range 1.94–2.08 Å, the O–Fe–O chelate ring angles are in the range 82.5–85.1°, with no apparent distinction between terminal and bridging chelates at the present stage of refinement, and the mean Fe–Fe distance is 3.15 Å for the two discrete dimer units. With the acetate considered to occupy the apical positions, the interplanar angle for the two basal planes is 150°. One piperidinium cation forms two intramolecular hydrogen bonds, whereas the other two cations bridge neighbouring $\bar{4}$-related anions. The overall structure can be described as rosettes of associated cations and anions, each containing four dimeric units arranged about the crystallographic $\bar{4}$ centres.

The burgundy-red crystals of the high base form have the composition $(C_5H_{12}N)_3[Fe(C_6H_4O_2)_3]\cdot H_2O$ and belong to the monoclinic space group $C2/c$ with $a = 22.887(4)$, $b = 11.747(1)$, $c = 23.999(3)$ Å, $\beta = 118.19(1)°$, $Z = 8$, $D_m = 1.29$, $D_c = 1.282$ g cm^{-3}; 6,320 X-ray reflections were collected of which 3,422 had $I > 3\sigma(I)$. The coordinates of all non-hydrogen atoms were determined using the direct phasing programme MULTAN[10] followed by several cycles of structure factor/difference Fourier calculations. Hydrogen atoms were positioned by calculation (O–$\underline{H}$ not included) and anisotropic refinement by full matrix least-squares methods resulted in a conventional R value of 0.054. The structure contains the expected 'propeller' of three bidentate catechol dianions, providing the octahedral coordination geometry $[FeO_6]^{3-}$ (Fig. 2*b*). Fe–O bond lengths vary between 1.991 and 2.036(8) Å, with a mean value of 2.020 Å. The O–Fe–O angles of the five-membered chelate rings, 81.1, 82.3 and 80.2(3)°, and the mean twist angle about the threefold axis, 46.4° (60° for a regular octahedron, 0° for a trigonal prism), reflect significant distortions from regular octahedral geometry. In the analogous potassium salt recently reported[11] the mean Fe–O bond length is 2.015(6) and the mean values of the O–Fe–O and twist angles are 81.26(7) and 44.7°, respectively. Considerably less distortion is found in the *tris*-catechol complexes of Cr(III) (83.56, 50.5°) (ref. 11), As(V) (88.2, 55.2°) (ref. 12) and P(V) (91.4, 54.9°) (ref. 13).

A comparison of the spectroscopic and magnetic properties given in Table 1 suggests that the monomeric, but not the dimeric, iron(III)–catechol complex is an appropriate model for the coordination geometry in iron(III)-enterochelin. Furthermore, these data suggest a similar electronic environment for the monomer and iron(III)-enterochelin. The ESR and Mössbauer data for the monomer are generally consistent with those reported for other iron-transport compounds but there are some differences in detail. Thus at 4.2 K in small applied fields (~2 koersted) the Mössbauer spectrum of the solid monomer does not display the degree of fine structure exhibited by that of methanol solutions of iron(III)-enterochelin[14]. The hyperfine field is also somewhat smaller in the monomer. Oosterhuis has recently given a detailed analysis of the ESR and Mössbauer spectra of iron transport compounds in terms of a rhombically distorted electronic model[15]. The crystal structure of the monomer certainly exhibits small variations in bond lengths and bond angles about the metal and in the pattern of hydrogen bonding to the phenolic oxygen atoms. The ESR spectrum for the dimer is complex showing transitions ranging from about $g = 5$ to 1, and the Mössbauer and magnetic susceptibility data are similar to those observed[16] for other exchange-coupled iron(III) dimers which normally have J values of the order of 10 cm^{-1} (ref. 6). Also all three complexes liberate three equivalents of Na$^+$ ion from Sephadex C-25 cation exchange resin from which they can be eluted with unchanged visible spectra. This apparent robustness in solution and in the solid state[17] together with the physical properties given in Table 1 strongly suggest a monomeric *tris*-catecholate coordination environment (Fig. 1*a*) for iron(III)-enterochelin.

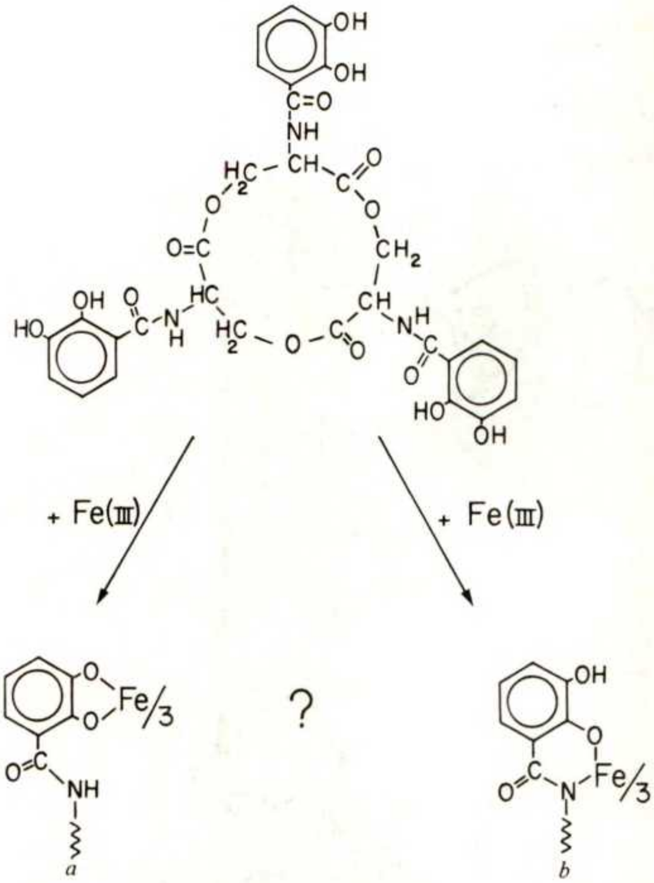

Fig. 1 Structure of enterochelin, the cyclic triester of 2,3-dihydroxy-*N*-benzoyl-1-serine[6], and two possible coordination geometries with iron(III). Coordination by way of the six catechol oxygens leads to a $[FeO_6]^{3-}$ unit containing three five-membered chelate rings (*a*), whereas coordination of a phenolate oxygen and a deprotonated amide nitrogen of each serine residue gives rise to a $[FeO_3N_3]^{3-}$ environment and six-membered chelate rings (*b*). Although the $[FeO_6]^{3-}$ coordination type has been proposed by several workers[1,6], it should be pointed out that all known phenolate siderochromes contain amide linkages to amino acids or amino acid fragments[1].

Table 1 Spectroscopic and magnetic properties of iron(III)-enterochelin and iron(III)-catechol complexes

	$[\text{Fe(III)-enterochelin}]^{-3}$	$[\text{Fe(catechol)}]^{3-}$	$[(\text{acetato})\{\text{Fe(catechol)}_2\}_2]^{3-}$
λ_{max}(nm) (ε/Fe)	496(5,600) (ref. 6)	496(4,700)	570(3,400)

§ P. D. W. Boyd and R. L. Martin, unpublished data.

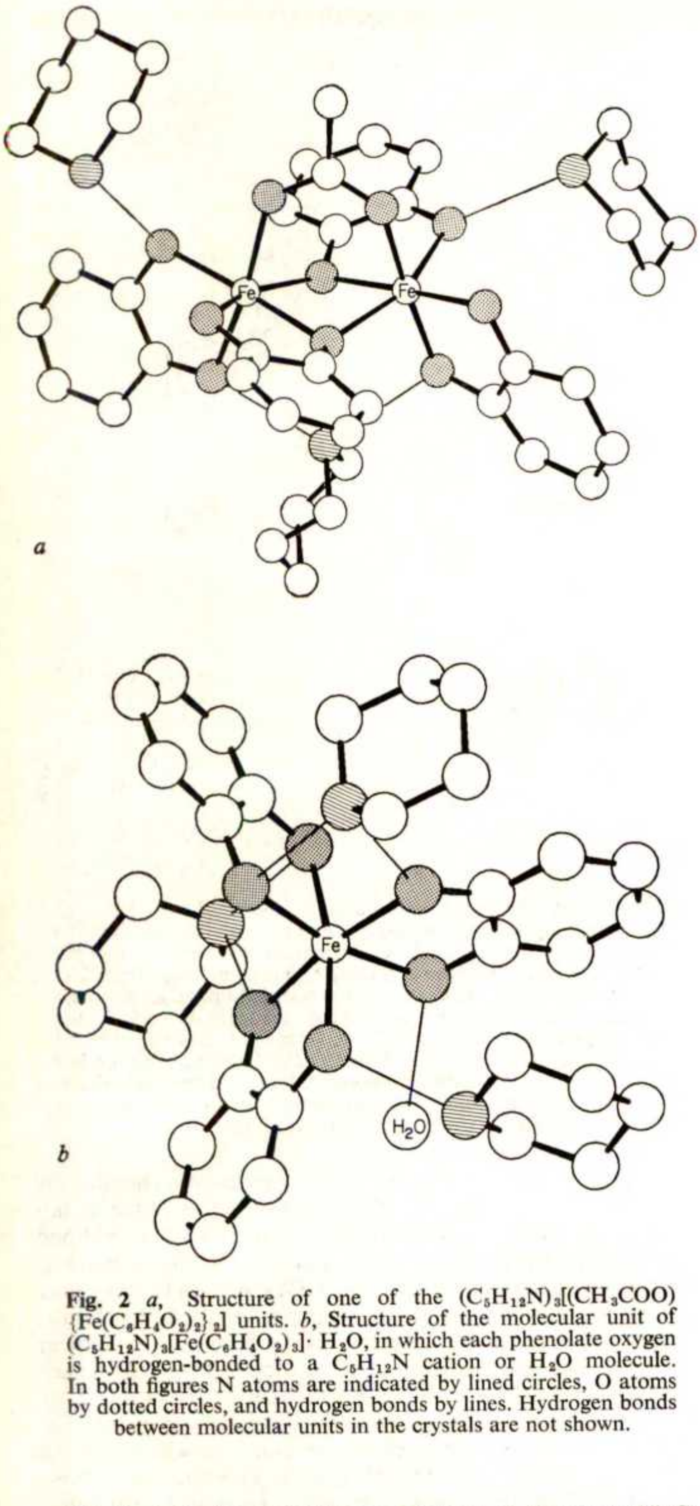

Fig. 2 *a*, Structure of one of the $(C_5H_{12}N)_3[(CH_3COO)\{Fe(C_6H_4O_2)_2\}_2]$ units. *b*, Structure of the molecular unit of $(C_5H_{12}N)_3[Fe(C_6H_4O_2)_3]\cdot H_2O$, in which each phenolate oxygen is hydrogen-bonded to a $C_5H_{12}N$ cation or H_2O molecule. In both figures N atoms are indicated by lined circles, O atoms by dotted circles, and hydrogen bonds by lines. Hydrogen bonds between molecular units in the crystals are not shown.

We thank Professor F. Gibson and Drs I. G. Young and I. G. O'Brien for assistance in preparing enterochelin and for other helpful advice. Iron(III)-enterochelin has been isolated from aqueous solution as the Ph_4As^+ or Ph_3MeP^+ salts. These compounds are very soluble in $CHCl_3$, CH_2Cl_2 and acetone, and may be readily converted to other salts by titration with the appropriate perchlorate salt (T. Rauchfuss, unpublished).

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* fits into four binders).
Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

matters arising

B-emission stars and X-ray sources

In 1975, an hypothesis of the binary nature of B-emission (Be) stars was proposed[1,2]. Referring partly to this and to the observed association of some X-ray transients with Be stars, Maraschi *et al.*[3] suggested that the classical Be stars, as the optical counterparts of the X-ray transients, could be responsible for the X-ray bursts of these objects. We present here some arguments against this interpretation.

Be stars are essentially normal, rapidly-rotating B stars situated (on average) about one magnitude above the main sequence in the Hertzsprung–Russell diagram. They are enclosed by an extended envelope producing emission (and sometimes also sharp absorption) lines in their spectra. The envelope lines usually exhibit several kinds of variability (for review see refs 1, 2): (1) long term profile and velocity variations, including sometimes even complete disappearance and reappearance of the envelope lines within 1–10 yr; (2) periodic velocity and profile variations with typical periods of 10–100 d; (3) rapid profile variations taking place within several hours or minutes. The main idea of the binary hypothesis of the Be phenomenon is that the Be envelope is formed as an accretion disk enclosing the mass-gaining components of certain mass-exchanging systems and that the high rate of rotation of Be stars is induced by infalling matter. Periodic velocity and profile variations are interpreted as reflecting the orbital motion while the long term changes are understood as consequences of varying rate of mass transfer between components (similar to the Algol binaries). This view is supported by observational data. In every known case, the basic properties of the Be stars recognised as binaries agree well with the theoretical predictions.

Maraschi *et al.*[3] suggested that the X-ray transients represent some later evolutionary stage of the Be binaries after mass exchange. In other words, they implicitly assume that the Be envelope once formed is a long lived phenomenon lasting even after the original mass-losing component has evolved to a compact object. They then interpret the X-ray bursts as a consequence of occasional infalls of matter from the Be on to the compact component controlled by some (unspecified) rotational instability of the Be envelope. There is no observational evidence to support this view. The long term variations of Be stars seem to indicate that the envelopes can dissipate rather quickly without the presence of a continuing supply of matter. Also, practically all known Be binaries exhibit clear signs of continuing mass transfer towards the Be component.

A more serious objection exists, however. It is important to realise that two groups of Be binaries are observed. In many cases, it is indeed the mass-gaining star enclosed by an envelope which dominates in the spectrum. Such a system can then appear as a 'single' Be star (ζ Tau, 4 Her or 88 Her can serve as examples). In other cases, however, it is the mass-losing star, which is the brighter of the two. But even then, some emission lines originating in the envelope around the (now invisible) mass-gaining star (or, alternatively, around the whole system) can be observed. If, at the same time, the mass-losing star is of a B type, such an object is often also classified as a Be star. This is the case of Be binaries HD 187399 (ref. 4) and HD 173219 (ref. 5), which are listed in all catalogues of Be stars. HD 72754, β Lyr, W Cru and probably X Per itself belong to the same category. This classification of Be binaries is convincingly documented by observations. Radical velocities of the hydrogen emission lines of all these objects invariably indicate that in any known case the emitting envelope does not enclose the mass-losing star—in clear contradiction to the expectations of the model of Maraschi *et al.*[3]. The Be stars assumed in that model do not seem to be identical to the Be stars normally observed and only by measuring the emission and absorption velocities of the X-ray transients can the existence of the objects postulated by Maraschi *et al.* be confirmed.

Environmental effects on alcohol selection by mice

Randall and Lester[1] attempted, by transplanting fertilised ova to mothers of a different strain, to estimate the relative contribution of heredity and environment to alcohol selection by mice. Their experiment was designed to allow the following comparisons of alcohol consumption to be made:

(1) *a*, Offspring resulting from the transfer of C57BL/6 strain ova to DBA/2 mothers were compared with *b*, offspring from C57 ova transferred to C57 mothers (control transplants) and with *c*, naturally bred (untreated control) C57 mice;

(2) *a*, Offspring resulting from DBA ova transferred to C57 mothers were compared with *b*, control transplant DBAs and with *c*, untreated control DBA mice.

The absence of a difference between groups *b* and *c* would imply that the transplantation procedure did not affect offspring and then a difference between groups *a* and *b* would imply that the maternal environment affects alcohol consumption of offspring. This pattern of findings is what they report: DBAs transferred to C57s and C57s transferred to DBAs showed increased alcohol consumption, findings which Randall and Lester conclude "uphold the hereditary basis of alcohol selection in C57BL mice, but show the avoidance of alcohol drinking by DBA mice to be amenable to environmental alteration".

Even if there were no questions about the findings themselves, there is no reason to regard an increase in consumption by one strain as less indicative of an environmental effect than the increase in consumption of the other. Both strains showed a similar effect.

It seems possible, however, that the composition of the *b* groups was not as represented. Randall and Lester state that experimental pups were identified by differences in eye pigment at birth. This method is liable to produce errors in identification, since both strains have pigmented eyes. Even if it was successful in the case of between strain (experimental) transfers it is difficult to see how it could have been used at all in the case of control transfers. The natural progeny of a C57 female mated to a C57 male will be indistinguishable from C57 transplants she has received (and, *mutatis mutandis*, the same problem arises with DBAs). It seems likely, then, that groups 1*b* and 2*b* consisted of both control transplants and natural offspring. Given the small yield of transplants (three or fewer per litter), it is also likely that a majority of pups identified as control transplants were instead natural offspring, equivalent, except for the surgical stress to the mother, to the untreated controls.

Uncertainty about the composition of the control transplant groups precludes any conclusion about the effects of maternal environment: the increased alcohol consumption of the between-strain transplants could equally well be due to the transplant procedure in general or the surgical stress it entails. In this latter case, *b* groups (stressed) should have differed from *c* groups (unstressed), which they did not. The stress to the mother is, however, confounded with the transplantation procedure (affecting the ova?) in the *b* groups; if the two events oppose each other in their effects, the offspring might not differ from naturally bred ones.

Unfortunately, the confounding of variables does not permit any definite conclusion.

Nancy Nettleton

Department of Psychology,
University of Vermont,
Burlington, Vermont 05401

[1] Randall, C. L., and Lester, D., *Nature*, **255**, 147–148 (1975).

Randall and Lester reply—We agree with some of the arguments presented by Joffe, Najman and Nettleton[1], but we take issue with others. The difference in eye pigment between newborn C57BL and DBA pups is obvious at birth: C57BL pups have dark black eyes and DBA pups have lightly pigmented eyes. While differences in coat colour become evident within a few days and could be used, eye pigment allows immediate identification and the early and accurate culling of the litter.

In control transfers (C57BL–C57BL and DBA–DBA), the pups are, obviously, indistinguishable. We could have used mates of the opposite strain to ensure identification of the transferred ova, but this approach has its own inherent problems; we could also have mated females to infertile males of the same strain, but this was not a preferable method: the female is only pseudopregnant, no control uterine horn is provided and the transferred offspring are not intermixed with natural offspring. We thus considered other controls; without prior knowledge of the outcome, we chose the method described in our paper. We do not deny the validity of the arguments against this approach: the possibility certainly exists that natural, rather than experimental offspring, were examined. These other control procedures can, of course, also be used to determine whether transplantation *per se* exerts no effect; should the results not agree, the issue would remain unresolved because of the differences in methods and the introduction of other confounding variables.

Preimplanted mouse embryos are resistant even to the most severe types of chemical and drug intervention, at least in regard to morphological development in a foster mother's uterus[2]. Runner[2] suggests that nucleic information is not integrated until implantation occurs. Rather than attributing the increase in ethanol intake to the transplantation procedure *per se*—because surgery is performed at least 2 d before implantation—it is more likely that the outcome is a result of critical mother–foetal interactions. This issue is unresolved, however, since we do not know whether biochemical changes associated with implantation and pregnancy are similar in natural and transplanted offspring.

Maternal surgical stress does not explain the increase in alcohol intake of transferred young, unless we assume that transplanted ova are differentially sensitive to subtle changes in the maternal milieu or to subsequent postnatal events. In unpublished pilot work, we found anaesthesia alone did not alter phenotypic alcohol intake. Further, natural offspring tested concurrently with transferred pups did not demonstrate an atypical strain effect. For the sake of brevity and because we regarded the data as superfluous, these data were not in our report; obviously, in retrospect, they should have been included.

We can hardly argue that the alcohol consumption of C57BL and DBA mice is not subject to environmental alteration because we have produced such alterations[3]. The issue raised here is, however, the contribution of genetic and maternal variables to the strain extremes, since differences in intake are evident at weaning. We argue that if alcohol selection were determined by maternal rather than by genetic inputs, we should observe selections resembling the phenotypic norm of the foster mother. We noted no such effects in either strain: although alcohol choice increased in DBA mice transferred to C57BL mothers, the offspring never demonstrated C57BL-like high selection of alcohol.

Our report cannot be read to exclude the importance of environmental variables in determining behaviour, although it assuredly emphasises that maternal behaviour is not as important a determinant of alcohol intake as is genetic constitution.

Molecular structure of NAD

Viswamitra[1] has speculated on the structure of free NAD which he then extrapolates to the NAD conformation when bound to enzymes. Unfortunately, he has neglected to take into account the extensive results which have been obtained during the past five years on the conformation of NAD when bound to lactate dehydrogenase[2], malate dehydrogenase[3], liver alcohol dehydrogenase[4] and glyceraldehyde-3-phosphate dehydrogenase[5]. Suffice it to say here that his speculations are inconsistent with facts and that the only 'fact' he does quote concerning the fit of his proposed NAD model to the low resolution difference map of Adams *et al.*[6] is incorrect.

[6] Adams, M. J., McPherson, A., Jr, Rossmann, M. G., Schevitz, R. W., and Wonacott, A. J., *J. molec. Biol.*, **51**, 31–38 (1970).

Viswamitra replies—The model proposed for NAD[1] was essentially for a free molecule. The reference to the work of Adams *et al.*[2] was to point out that NAD conformations with the adenine and nicotinamide bases far apart had been considered earlier. Although the statement about the possible compatibility of the model with the low resolution electron density maps of Adams *et al.* was unfortunate, it was only made as it was felt that electron density maps at 5-Å resolution, could admit, in general, a certain flexibility where the derivation of the shape of a small substrate molecule is concerned. It is also difficult to rule out conformational states of coenzyme molecules other than those derived from structural studies of bound enzymes as inconsistent with facts. The molecular structures found for ADP in the crystal structure of its rubidium[3] and *tris* salts (M.A.V., Z. Shakked and O. Kennard, to be published) are different from those deduced for the coenzyme from structural studies of bound enzymes[4].

reviews

Genuine passion for research

E. H. S. Burhop

Frederic Joliot-Curie : A Biography. By Maurice Goldsmith. Pp.260. (Lawrence and Wishart : London, June 1976.) £6.

Courtesy Association Joliot-Curie

At a memorial meeting for Rutherford (November, 1947). Left to right: Desmond Bernal, Joliot-Curie, and Lady Rutherford

To the genuine scientific research worker there is no greater satisfaction than that of discovery. Frederic Joliot-Curie was just such a man with a genuine passion for research. In addition he was an unusually fine and talented craftsman, skilled with his hands and appreciative of beauty in technique no less than in art. He was married to Irene, daughter of Pierre and Marie Curie, born and bred to the laboratory and the exacting standards of scientific integrity and hard work, as well as the vision that characterised the work of her famous parents. There are three great highlights in the scientific work of the Joliot-Curies.

In 1931 they observed that a penetrating radiation emitted when beryllium was bombarded by α particles was capable of ejecting energetic protons from a thin layer of paraffin wax. They erroneously interpreted the penetrating radiation as due to 50 MeV nuclear γ rays but this was an unlikely explanation; and Chadwick, as soon as he heard of the work of the Joliots repeated it and established conclusively that the radiation consisted of neutrons, for which Rutherford had been searching for 13 years. For this Chadwick received the Nobel prize.

In 1934 they discovered the new phenomenon of artificial radioactivity, showing that light elements bombarded with α particles could be made radioactive, emitting positrons with characteristic half-life. For this discovery they shared a Nobel prize in 1935, just 32 years after a similar joint award to Irene's parents.

In 1939 Joliot and his colleagues studying the newly discovered process of nuclear fission after the capture of a neutron by uranium, showed that more than two neutrons were emitted in the subsequent fission, thus establishing the possibility of initiating a nuclear chain reaction and, incidentally, although they did not realise it at the time, of the breeder reactor.

Frederic and Irene Joliot-Curie could no doubt have derived the greatest satisfaction and sense of fulfilment from continuing to work together in their laboratory for their whole lives. But they shared in their family backgrounds the finest traditions of French radicalism. They were conscious of the power of science and technology to provide the material basis on which a transformation of society could be effected. The reality they saw was of a society in which science was underused or misused, with poverty, unemployment, inequality, threatened internally and externally by fascism. War came and with it humiliation for their country.

Can a scientist remain tied to his laboratory, indifferent to what is going on about him in such circumstances? Or if he can, should he? The life of Frederic Joliot-Curie epitomises the problem of the social responsibility of the scientist. It is a tribute to Maurice Goldsmith that in this short and brilliantly written biography he not only captures the excitement and drama of the scientific discoveries to which the Joliot-Curies contributed in such ample measure. He also brings out the significance of the decisions Joliot had to make and the deeper meaning of his life.

Joliot-Curie had, no doubt, what the answer to the above rhetorical question should be. He would have accepted the viewpoint of Paul Langevin, his teacher and friend: "I must devote myself to these political activities. It is true that I could be doing my science, but the science I could do will be done by others, and this task comes to me because it is not being done by others".

Joliot's sense of social concern led him along a hard and stony path, to great misfortune, and possibly to premature death for his wife and himself. He became Head of the World Peace Council. The great Stockholm Peace Appeal against nuclear weapons, signed by 500 million people throughout the world was his brainchild. This built up such a worldwide public reaction against nuclear weapons that it made the idea of a pre-emptive nuclear strike, for which some 'hawks' were clamouring, unthinkable. He became President of the World Federation of Scientific Workers which had been set up under the influence of scientists like Joliot, Langevin and Bernal to try to ensure effective planning, policy making, peaceful application of science, and proper training and conditions of work for scientists. Joliot first raised with Bertrand Russell the possibility of the organisation of a world conference of scientists against nuclear weapons which eventually led to the Pugwash Conferences. The first contacts of the reviewer with both Joliot and Russell were connected with this initiative.

In the post-war period, alongside activities of this kind, Joliot was deeply involved in questions of French science and nuclear energy policy. Soon after the liberation of France he was given the task of reformulating science research policy. He reorganised the National Fund for Scientific Research (CNRS), laying a basis for French scientific research that persists today. On the setting up in October 1945 of the French Commissariat for Atomic Energy, Joliot was appointed its High Commissioner and in this capacity was responsible for planning the highly successful first decade of the French peaceful nuclear energy program.

But Joliot's increasing commitment to the struggle against nuclear weapons led to a virulent campaign against him in the French press and increasing pressure on the French Government to dismiss him. Eventually in 1950 his one time friend and colleague in the Resistance, Prime Minister Georges Bidault, delivered the *coup de grace*.

Joliot was a sensitive man and his dismissal and the abusive and deeply wounding insinuations that accompanied it saddened his last years. Certainly Irene, to whom he was devoted, and possibly he himself, suffered from the effects of radiation. He died in 1958, surviving Irene for two years.

This is a significant book and successfully portrays the warmth, greatness and vision of its subject. Some parts read as excitingly as a detective novel, as when it describes how Joliot's foresight and initiative led to his arranging for France to acquire the whole Norwegian stock (~ 180 litres) of heavy water to prevent its falling into German hands; and then arranging for its transfer to Britain, just ahead of the Nazi invasion of France. This was a signal contribution to the Allied cause for which he received scant recognition when he was refused permission to enter Britain in 1950 to attend the Sheffield Congress of the Partisans of Peace. Again there is the account of his courageous work in the French resistance, especially in the preparations for the Paris rising of 1944, for which his laboratory organised the supply of munitions.

But the key question that will be raised by the book and one that still confronts us today is the way in which the scientist must reconcile his duty to his profession of scientific research worker with his responsibility to society as a whole. Joliot had to make this decision under circumstances of very great difficulty and there will certainly be differences of view concerning the correctness of his choice. If, however, the 500 million signatures of the Stockholm Peace Appeal helped significantly to prevent the further use of nuclear weapons then surely one must conclude Joliot's choice was the correct one. ☐

Professor E. H. S. Burhop, FRS, is Professor of Physics at University College, London, UK. He was associated with F. Joliot-Curie in the World Federation of Scientific Workers and eventually succeeded him and C. F. Powell as President.

Marine mussels

Marine Mussels: Their Ecology and Physiology. (International Biological Programme 10.) Edited by B. L. Bayne. Pp. xviii+506. (Cambridge University: Cambridge and London, June 1976.) £22.

THIS excellent volume is strongly recommended for purchase by universities, polytechnics, museums, and marine biological research stations, on a worldwide basis. It will be an indispensible tool for professional biologists who are concerned with biology of bivalve molluscs, or productivity of coastal waters, and who can afford the price. It will form a stimulating basis for university courses in marine biology.

The editor and authors are to be commended for their lucid, narrative style, for every chapter makes interesting reading. The authors' authority lies in their own contributions to the literature. They comprise: Sir Maurice Yonge (The 'mussel' form and habit); R. Seed (Ecology); D. Roberts (Mussels and pollution); B. L. Bayne (The biology of mussel larvae); B. L. Bayne, R. J. Thompson and J. Widdows (Physiology I, II, Physiological integrations); P. A. Gabbott (Energy metabolism); J. S. Levinton and R. K. Koehn (Population genetics of mussels); J. Mason (Cultivation).

Mussels have a global distribution in coastal waters and estuaries, and provide a major part of the world crop of bivalve shellfish; and they are important components of their ecosystems. The book deals with the whole range of biology of mussels—how their physiological attributes equip them for their environments and the variables with which they contend. We are informed on the biology of mussel larvae, their food preferences, primary settlement, and subsequent movement to beds of adult mussels. Growth rates at different tidal levels, predators, and parasites, are considered in turn.

Physiology of nutrition, and respiration, and the functioning of the vascular and excretory systems are studied in depth. Physiological features are related to the ecological setting—for example, the ability of mussels to acclimate their filtration rate and oxygen consumption (but not heart beat) to short-term fluctuations in temperature and ration.

Seasonal changes in biological composition of mussel flesh, food reserves, metabolic pathways, and control mechanisms are considered, the last with reference to compensation for environmental change. Population genetics, with reference to isoenzymes, reveals variation on a geographic scale, and also on a small scale within an estuary or tidal flat.

Consideration is given to pollutants, and to purification before marketing; care must be taken against paralytic shellfish poisoning arising from unusual blooms of *Gonyaulax* or *Gymnodinium*. The book ends with a review of mussel cultivation in Western European seas.

The book is illustrated by 142 text figures which are commendably clear; most of these are graphs and line diagrams, but there are also some good photographs. The reference list, which must contain about 1,500 entries, will be a valuable tool in itself. There is a good index.

Typographical errors are rare. The Reviewer regrets the general misuse of the word 'visualisation' by chromatographers, and the increasing mistreatment of 'data' as a singular noun; and he is disappointed to find both these usages here. What, incidentally, is 'vagile' (p 358)—it is not in the reviewer's copy of the Shorter Oxford English Dictionary. **R. D. Purchon**

R. D. Purchon is Professor of Zoology in the University of London, Head of the Department of Zoology at Chelsea College, and presently the Chairman of the Biological Sciences Group of Departments at Chelsea College, London, UK.

Primitive sensory systems

Primitive Sensory and Communication Systems: The Taxes and Tropisms of Micro-Organisms and Cells. Edited by M. J. Carlile. Pp. vii+258. (Academic: London, New York and San Francisco, January 1976.) £8.50; $21.

THERE has been a renewed interest and considerable progress in the study of cell orientation, and this compact book shows some of the new results and the new excitement. If I had any criticism, it would be one of omission rather than what the book contains.

It starts off with a clear and systematic introductory essay by M. J. Carlile. The effects of light on orientation are treated in an organised fashion by W. Nultsch. Julius Adler provides a short, lucid review of his own beautiful work; I am only sorry he did not go into further detail, especially on the work of Berg, Koshland and others; but there are a number of other good recent reviews on this subject published elsewhere. T. M. Konijn provides the best review I have seen anywhere of all the work on cellular slime mold chemotaxis, and I feel equally enthusiastic about G. W. Gooday's review of chemotaxis (and tropisms) in the algae and fungi.

Finally, P. C. Wilkinson provides a brief review of the work on leukocyte chemotaxis which is succinct and clear, as one would have expected if one has read his fine book on the same subject. He stresses the point that macromolecules seem to be important leukocyte attractants, which contrasts with the role of small molecules as attractants in the earlier chapters.

Besides more on bacterial chemotaxis, I would have liked to see a review of all the work on pollen tubes; it would have fitted in well. I also missed a concluding chapter which might have attempted to bring together some of the photo- and chemo-orientation ideas, as well as some of the common and contrasting details in the different chapters. But perhaps these complaints are merely an indication that I found myself stimulated (and oriented!) by the book.

J. T. Bonner

J. T. Bonner is Professor of Biology at the University of Princeton, New Jersey.

Radiation and matter

The Dynamics of Spectroscopic Transitions: Illustrated by Magnetic Resonance and Laser Effects. (Wiley-Intersciences Monographs in Chemical Physics.) By James D. Macomber. Pp. xxiv+332. (Wiley-Interscience: New York and London, February 1976.) $23; £11.50.

THIS book is concerned with the mechanisms by which radiation can interact with matter and, in particular, with the processes involved when electromagnetic radiation stimulates a transition from one quantised energy level to another. The author points out that discussions of the physical principles involved are often omitted in books on spectroscopy and has directed this book at advanced undergraduates, graduates and research spectroscopists. The first three chapters outline the essential quantum theory and theory of electromagnetic radiation that is required. Chapters 4 and 5 give the theory of the interaction of radiation with matter, and in chapter 6 the theory is ilustrated with reference to magnetic resonance; in this area the physical principles are particularly easily understood. In the last two chapters the theory is generalised to other systems and to two-level systems.

The subject inevitably requires mathematical treatment, and this is set out very clearly in the book. At the same time the author is at pains to give, wherever possible, physical explanations of the processes involved. These are often of great value in thinking about spectroscopic experiments, and many spectroscopists would find much to fascinate and enlighten them.

I was a little surprised to find in the historical introduction no mention of Purcell, Torrey and Pound as discoverers of magnetic resonance in bulk matter at the same time as Bloch and his colleagues. There are one or two minor and obvious errors (for example in Fig. 4.3), but these do not significantly mar a clear and lucid account of an important aspect of spectroscopy.

R. E. Richards

Dr Richards is Warden of Merton College, Oxford, and Chairman of the Oxford Enzyme Group working in the Department of Biochemistry at the University of Oxford, UK.

Trace elements

Trace Element Analysis. By V. Valkovic. Pp. x+229. (Taylor and Francis: London, November 1975.) £7.

Trace Element Analysis is a unique book as far as its content can be judged in relation to its title. There are many books which treat techniques of trace analysis in monographic form or are devoted to a wide range of physicochemical techniques but which in general say little about the reasons or rationale for doing such work. This slender attractive volume does set out to describe *some* techniques, but concentrates to an unusual degree on setting the scene and giving the background to the philosophy and fundamental reasons for the importance of analysing for trace elements under particular sets of circumstances. This part of the book is extremely well done and the author is to be congratulated on his grasp of such a wide field of knowledge and his ability to write in such an interesting way. This part of the text (128 pages) occupies the first six chapters: elements in nature; trace elements in the environment; environmental pollution; trace elements in biology and medicine; general aspects of trace analysis.

The remaining 67 pages are devoted to chapters on activation analysis, X-ray emission spectroscopy, optical methods and mass spectrometry. Here the book is not quite so satisfactory in that the treatment is more restricted and a good deal less detailed and rather less critical in its assessment than other books which are available. It is, for example, disappointing to find no mention of work on electroanalytical techniques of trace analysis and scant attention given to the preconcentration techniques that are so important to trace analysis in all its guises. Some of the descriptions of atomic spectroscopic techniques are also rather outdated and oversimplified.

The strength and the excellence of this book lies, however, in the first six chapters which are unusually good and make it a worthwhile text for all who are concerned with the broader aspects of trace element analysis.

T. S. West

Professor West is Director of the Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen, UK.

obituary

Georgii Samsonovich Dzotsenidze, the eminent Soviet geologist died on May 5, 1976, aged 66.

Dzotsenidze was born in 1910, in the Georgian town of Kutaisi. He was educated at Tbilisi University, graduating in 1929, and from then on his academic career was closely connected with the University, rising from the position of laboratory assistant in the Department of Mineralogy and Petrology, to become a lecturer, Dean of the Faculty of Geology and Geography, and finally, in 1958, Rector of the University. His research was concerned mainly with the geology of Georgia; in 1933–34 he led the geological survey team of the Georgian Geological Board. His more than 120 publications include *Premiocine extrusive vulcanism of Georgia*, *Question of the genesis of barytic deposits in Georgia*, *Analcite level in the coal–bearing formation of the Kutaisi–Gelat region*, and *Petrology of the Bath Deposits of Okribri*. He was elected a full member of the Georgian Academy of Sciences, having served for four years as acting Academic Secretary of the Academy. In the same year (1955), he became a Vice-President of the Georgian Academy of Sciences. In 1968 he became a full member of the Academy of Sciences of the USSR.

Dzotsenidze combined his academic career with considerable political activity. He served as a Deputy of the Supreme Soviets of the Georgian SSR and the USSR several times, and was a member of the Central Revision Commission of the CPSU and of the Central Committee of the Communist Party of Georgia.

For his academic and political activities Dzotsenidze received a number of high Soviet honours, including the Order of Lenin (three times), the order of the October Revolution, the Order of the Red Banner of Labour, a Stalin (now State) prize, and numerous medals.

announcements

The **1976/77 Moscow Seminars on Collective Phenomena** will take place on Sundays at 1200 starting on September 12, at Ulitsa Veshnyakovskaya, Dom 4, Korpus 2, Appartment 5, Moscow. Letters, reprints and preprints may be sent to **Professor M. Ya. Azbel'** at the above address, but all correspondence must be registered and insured. All visiting scientists are very welcome to attend the seminars unannounced.

The programme is:

September 12, 1976: Dr Yu. Mniukh on **Polymorphic Transitions in Crystals.**

September 19, 1976: Professor Yu. Orlov on **Wave-logic and its Applications to Wave-Mechanics.**

September 26, 1976: Dr A. May on **Cybernetic Ideas and Empirical Sociology.**

October 3, 1976: Corresponding Member B. Levich on **The Semi-empirical Theory of Turbulence.**

October 10, 1976: Professor M. Ya. Azbel' on **Decoding DNA.**

October 17, 1976: Dr I. Andryukin on **The Theory of Exactness of Mechanical Treatment.**

October 24, 1976: Dr E. Trifonov on **Genetic Engineering.**

October 31, 1976: Dr G. Rosenstein on **Models of Mental Distress.**

November 7, 1976: Dr V. Brailovsky, on **Deducing Relationships from Experimental Data.**

November 14, 1976: Professor N. Salanski on **Physics of Magnetic Films.**

November 21, 1976: Dr Yu. Kalenov on **Hydrodynamic Lasers.**

November 28, 1976: Dr V. Lazaris, on **The Creativity of Ben Galevi.**

December 5, 1976: Professor Ya. Alpert on **Wave-Phenomena in Cosmic Plasmas.**

December 12, 1976: Dr A. Kaplan on **Dynamics of Quantum Systems in a Non-linear Resonance Field.**

December 19, 1976: Professor N. Meyman on **Spectral Properties of the Schrödinger Equation in a Periodic Field.**

December 26, 1976: Professor B. Fain on **An Experimental Investigation of Psychological Pecularities.**

January 2, 1977: Dr I. Brailovskaya on **Supersonic Viscous Flow Around a Body.**

January 9, 1977: Dr I. Gildengorn on **The Influence of Oxidation on Thermoelectric Properties of Alloys.**

January 16, 1977: Dr M. Shepelev and Dr V. Dubrovskaya on **The Order of Reaction in Vulcanisation of Rubber.**

January 23, 1977: Professor A. Tzinober on **Hydrodynamics of Liquid Metals in a Magnetic Field.**

January 30, 1977: Professor N. Salansky on **Yoga and Judaism.**

February 6, 1977: Corresponding Member B. Levich on **Electrocapillary Phenomena.**

February 13, 1977: Professor M. Ya. Azbel' on **Entropy and Phase Transitions.**

February 20, 1977: Dr A. Schuster on **An Optical Problem in Combination Theory.**

February 27, 1977: Dr G. Shapiro on **Hormonal Regulation of Vital Functions.**

March 6, 1977: Dr L. Regelson on **Interaction of Weak Fields with Biological Structures.**

March 13, 1977: Professor N. Meyman on **Dispersion Relations and the Flow Increase Principle.**

March 20, 1977: Dr V. Retz on **Determination of the Electronic Density Function of Protein.**

March 27, 1977: Dr L. Vilenskaya on **Possible Interpretation of some Psychological Phenomena.**

April 3, 1977: Professor M. Kovner on **Earth's Radiative Belts and their Origin.**

April 10, 1977: Dr A. Kaplan on **Non-linear Fresnel Reflection.**

April 17, 1977: Professor S. Alber on **Asymptotic Methods in the Theory of Eigenvalues.**

April 24, 1977: Dr E. Tzifonev on **Evaluation of Nucleotide Sequences (Experimental).**

May 1, 1977: Professor B. Fain on **Non-radiative Transitions in Condensed Matter.**

May 8, 1977: Corresponding Member B. Levich on **Surface Turbulence in a Liquid.**

May 15, 1977: Dr G. Volk on **Viscosimetric Determination of Molecular Weights.**

May 22, 1977: Dr A. Dolgopolsky on **The Hebrew Language and Alphabet: The History of Languages.**

May 29, 1977: Professor M. Ya. Azbel' on **New Statistics of Quasiparticles.**

June 5, 1977: Dr A. Malitzky on **The Planning of an Experiment.**

June 12, 1977: Dr E. Tzifonev on **The Spatial Structure of RNA.**

To get to Professor Azbel's apartment: Take the Metro to Zhdanovskaya (end of line in Eastern suburbs), then the No 64 Trolleybus North along Ulitsa Veshnyakovskaya until the road forks (about 6 stops).

nature

August 26, 1976

Which way now for journals?

Barnaby Rich said in 1613 that: "One of the diseases of this age is the multiplicity of books; they doth so overcharge the world that it is not able to digest the abundance of idle matter that is every day hatched and brought forth into the world". He would undoubtedly have used similar words in 1976 to articulate the concern that most practising scientists express from time to time about the proliferation of journals and the number of papers published, but perhaps he would also have come up with some practical suggestions about how the problem should be solved in the light of diminishing library budgets. It is really only when a university library, say, cuts out by mistake what a substantial number of people regard as a vital journal that there is any significant outcry.

Interestingly, though, only about 55% of the expenditure of a typical university library on journals (in the UK at least) is devoted to 'essential' titles. The remainder are 'desirable' or 'marginal', spending on these categories being 40% and 5% of the total, respectively. If the coming academic year proves to be another tough one financially, marginal titles are likely to become a thing of the past, and the list of desirable ones will be on the chopping block, So if things don't get any better for libraries, what is to be done?

First of all, one might wish for an unwritten rule that the creation of a new journal had to be a true reflection of the appearance of a new subject grouping or synthesis of subjects, and not merely a rather meaningless subdivision of an old subject. (No marks out of 10 for *Slide Rules in Laryngology*, for example.) And on this basis, why not aim to have two journals shut down for every one started? (True, this would imply the publication of fewer papers, but that would be no bad thing in the light of claims that more than 90% of papers written eventually get published somewhere.) The plain facts of the matter, however, are that of about 35,000 journals in existence at present, only 1,300 disappear each year whereas a full 2,000 are added.

Second, as the pious hopes of the previous paragraph can at best be only partly realised, what can be done to existing journals to reduce their bulk and their cost? The bulk is particularly important both because it determines how much the reader has to read, and because postage is now such an important element (some 15% of the cost of a subscription to *Nature* in the UK, for example).

One of the ultimate solutions is to publish a journal solely in microform—probably microfiche, a single piece of photographic sheet film some 10 × 15 centimetres containing reduced images of 100-odd journal pages. There are no paper or machining charges and minimum postal costs—but the spectre of user resistance rears it head. How can we browse in a library that uses uninviting gadgetry like a microfiche reader, they ask. It seems that nobody is ready yet for a complete revolution like that, however, and maybe they never will be. Microform for archival use, yes; for current use, probably no.

So what are journal publishers (which include many learned societies, large and small, as well as commercial concerns) to do? The most accurate indicators of current thinking are the experimental publishing projects being carried out by the Chemical Society in the UK and the American Chemical Society in the United States. These cautious steps forward involve what are called 'synopsis journals', in which the author writes a synopsis of perhaps 1,000 words, which is printed conventionally and backed up by more detailed information, on microfiche for example, to which the reader can have access if he requires.

As the microfiche part of such a journal can make use of directly photographed typewritten pages while the synopsis part can still be printed in a way that makes it look no different to a comparable publication, the average reader, who likes his journal to look 'right' and to be printed on good old-fashioned paper, can be tempted to move in the right direction without sacrificing any of the things he holds dear. The librarian, for his part, would hope to see the changes reflected in the subscription price.

The browsing reader can still browse in the time-honoured way, with the added advantage of not having so much to read or skim through. Those who need to consult the back-up information will only have to suffer microform in pursuit of the small number of papers that directly interest them and ought not to find its use an excessive chore in these circumstances. In fact, if one believes the tales that most papers are only read in detail by one or two people, it could turn out that librarians in a synopsis era would find relatively little call on their microfiche facilities for this purpose. Which raises the whole question of whether all that detail actually needs to be published at all. Could it not equally well be submitted for scrutiny by the referee and then made available by the author to those who care to request it?

Tennessee valley energy

The Tennessee Valley Authority represents an American historical landmark. **Colin Norman** reports

WHEN the Tennessee Valley Authority (TVA) was established in 1933, at the height of the great depression, it rapidly became one of the more controversial instruments of President Franklin D. Roosevelt's famed New Deal. Designed, in Roosevelt's words, for the reclamation of land and of human beings, the creation of TVA was a unique federal attempt to attack the grinding poverty of an entire region by developing and conserving its natural resources.

Like much of the New Deal, the experiment was controversial because it went against the capitalist grain for the federal government to play such a strong role in economic and social enterprises. To many conservatives, it smacked of socialism. Now, 43 years later, TVA is still controversial, though for different reasons.

In 1933, the Tennessee Valley was an economic and environmental disaster area. Most of the region's people were at the bottom of the pile, living in desperate poverty. The land, which had been worked to death, was fast being eroded and turned into a barren waste. The hillsides, which once boasted the largest hardwood forests in North America, were denuded. And the 1,000-mile Tennessee River would frequently burst its banks, flooding vast areas; in many places, shoals and shallows also made it impossible to navigate. Then along came TVA's armies of engineers, scientists and agriculturalists to dam up the rivers, reforest the hillsides and reclaim the land. By most measures, they have been spectacularly successful.

Although family income in the region is still a little below the national average, it is no longer an economically depressed area. It has a productive agricultural system and industries have been attracted into the area by cheap electricity rates. And the Tennessee River has been tamed by numerous dams, so that it is navigable and it no longer rampages through the fields and towns each spring. The stark before-and-after contrast in the valley in fact gradually made true believers of all but the most diehard conservatives.

Consequently, TVA is now held in the highest regard by many of the people who live in the seven-state area which it serves, a fact painfully discovered by Senator Barry Goldwater in 1964 and by Ronald Reagan a few months ago. Both hinted that, if elected President, they may consider selling TVA off to private industry to get rid of this socialist monstrosity. They paid dearly at the polls as a result, losing important elections in Tennessee.

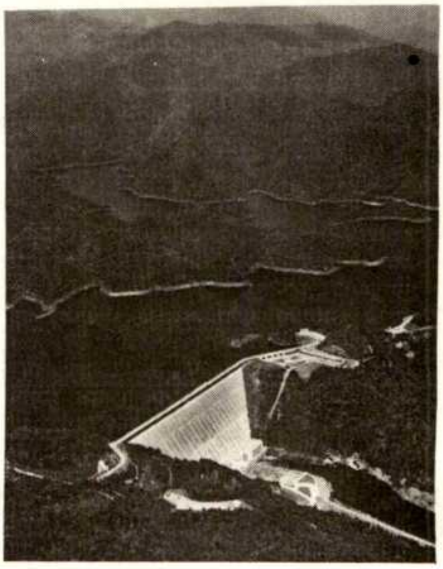
Highly charged issues

TVA is controversial now because it is facing many highly charged issues endemic to an industrial society, such as energy planning, strip mining, air pollution, and public participation in governmental decision-making. The sheer scale of TVA's operations ensures that the way it tackles those issues often has national implications.

A description of TVA's activities reads like a list of superlatives. It is the largest energy supplier in the United States, providing electricity to a region the size of Great Britain. It is the single largest user of coal in the nation, consuming more than 40 million tons a year in its power plants. It has more nuclear power plants under construction than any other electric utility. The 33 major dams which have been constructed on the Tennessee River and its tributaries harness lakes whose combined shorelines are longer than those of the Great Lakes. And it is the region's largest employer, providing 31,000 jobs.

Even the criticisms being levelled at TVA are impressive in their scope. During Senate testimony on TVA last year, for example, one critic suggested that "the Tennessee Valley Authority is a part of the problem in Appalachia, not a part of the solution", while another stated that TVA "began as an experiment in democracy but has turned into an example of how our government can practise colonialism on its own people".

TVA is really two separate operations. One, financed entirely by federal appropriations of more than $100 million a year, is responsible for running a vast range of programmes, including agricultural assistance, fertilizer research and development, and the management of parks, dams and recreational facilities. The other, more controversial, side of TVA's activities is its role as supplier of electricity to the region. It is a self-supporting, $1,000 million-a-year operation, financed by revenues and by the sale of bonds for capital projects.



Fontana dam, the TVA's highest

Problems, controversies

The problems and controversies encountered by TVA's energy operations are similar to those being faced by other electric utility companies, but TVA's unique structure gives it some advantages in tackling them. For one thing, the agency's Congressional charter requires that it be run as a nonprofit enterprise, which means that it doesn't have to pay dividends to stockholders. It is also fortunately situated right next door to the Appalachian coal fields, and its numerous dams provide a secure source of cheap electricity. For those reasons, TVA's electricity is the cheapest in the country, selling at about 60% of the national average.

At present, about 20% of TVA's power comes from hydroelectric sources, and the rest comes from coal-fired power stations. A few years ago, however, the agency decided that all its future energy growth would come from nuclear power plants, and it embarked on a massive nuclear construction programme. By the mid-1980s, TVA expects to have 17 nuclear reactors in operation at seven different sites, adding up to a staggering 20,000 MW. It would be the largest user of nuclear power in the country. Clearly, TVA's espousal of the atom, at a time when many other electric utilities are deferring or cancelling their nuclear orders, has enormous impact on the United States nuclear power programme.

Why does a utility which is sitting on top of a vast coal field decide to go nuclear? TVA has already dammed up most of the rivers in the region so that there is virtually no scope for expanding its hydroelectric generating capacity. "The choice is between coal and nuclear", says TVA General Manager Lynn Seeber, "and we believe that nuclear will be cheaper and environmentally more acceptable". The agency's critics disagree, however, pointing out that TVA's brief experience so far with nuclear power has been disastrous—it owns and operates the Browns Ferry plant which caught fire last year—and the critics also argue that the cost estimates will prove to be grossly inaccurate.

Be that as it may, environmental factors clearly played a key role in TVA's decision to opt for nuclear power instead of expanding its coal-fired generating capacity. In short, federal pollution control regulations are becoming more and more expensive to meet, particularly since TVA recently lost a major court battle with the Environmental Protection Agency (EPA).

Regulation problems

The pollution control regulations which are causing TVA most of its problems are embodied in the 1970 Clean Air Act, a bill which sets air quality standards and a timetable for meeting them. In some places, the Act is a little fuzzy in its definitions, and there has been a royal battle on several fronts over compliance with the standards. TVA decided early on that it could meet the regulations by a combination of tall smokestacks on its power plants, and continuous meteorological monitoring to ensure that the pollutants are not blown back to the ground in large concentrations.

It developed a sophisticated forecasting and monitoring system which would automatically give orders to curtail, or shut down entirely, individual power plants when meteorological conditions prevent proper dispersal of the stack gases. TVA has recently computerised the entire operation.

EPA interpreted the Clean Air Act differently, however, insisting that it requires stack gases, such as sulphur dioxide, to be removed entirely. Simply spewing them into the atmosphere through tall stacks will cause problems downwind, when the SO_2 is washed out of the atmosphere as so-called acid rain, EPA argued. As usual in such matters, the dispute ended up in the courts and the outcome was closely watched by environmentalists and by industry since it represented a crucial test of EPA's strategies.

TVA lost the battle earlier this year. According to TVA officials, it will cost about $250 million a year to install and operate the required pollution control equipment on several power plants. By contrast, TVA's proposed meteorological approach would have cost about $20 million a year.

And there have been other problems with TVA's heavy use of coal. For one thing, coal prices have escalated from about $10 to $30 per ton in the past three years. And for another, most of TVA's coal comes from strip mines, which are causing considerable environmental destruction and bitter resentment in some areas of Appalachia.

Although TVA officials take deserved pride in the fact that all their contracts with coal suppliers contain a clause requiring that strip mined lands be restored and revegetated, it's clear from testimony before a Senate committee last year that those requirements haven't always been met. "We can show anyone who would like to tour our area that TVA has never strictly enforced their regulations against certain operators", says J. W. Bradley, President of a group called Save Our Cumberland Mountains. Bradley went on to describe how "with every turn of the dozer's track and every bite taken by a large shovel, dragline, or front end loader, and by every blast of dynamite, we are furnished with more and more polluted water, fractured rock, loss of land and vegetation." Clearly, whatever requirements are imposed, TVA has been responsible for supporting a vast amount of strip mining, a practice which some regard as being unacceptably destructive.

Nuclear future

Those are some of the factors which have led TVA to seek a nuclear future, but it has found that it has in some respects traded one type of problem for another. So far, TVA has completed two of three units at the Browns Ferry nuclear plant, and four more units—at the Sequoyah Nuclear Plant and the Watts Bar Nuclear plant—are expected before 1980. All have experienced cost overruns, and the fire last year at Browns Ferry was a considerable setback. Started by an electrician checking for air leaks with a candle, the fire knocked out several safety systems, came close to causing a nuclear accident (how close is a matter of debate), and has so far shut down the plant for about 16 months. According to Seeber, the fire has cost TVA about $100 million in repairs and lost time.

TVA is, however, fortunate in one respect. There is little grass roots opposition to nuclear power in the region, and there have been few delays caused by anti-nuclear groups forcing public hearings and challenging power plant plans in court. In part, the lack of opposition can be explained by the fact that the area has always been associated with nuclear power through the Oak Ridge National Laboratory, which provided the plutonium and enriched uranium for the Manhattan Project and which is still a major nuclear facility.

Whatever the problems, TVA has so far shown no sign of backing off from its commitment to nuclear power. In fact, it has taken two steps to enhance its nuclear future. It is now investing heavily in uranium exploration in the Western states, with a view to securing uranium supplies. And it is a major partner in the liquid metal fast breeder reactor programme, providing some money and other support for the demonstration plant to be built at Oak Ridge.

TVA domination

Aside from the controversies over TVA's energy planning, there's one broad factor which seems to bother some people living in the Tennessee Valley. TVA's operations are so extensive that it literally dominates much of the economic life of the region, and there seems to have developed a feeling that it has become a faceless bureaucracy unresponsive to local needs. The chief problem is that TVA

Watts Bar nuclear plant

is a federal agency under the control, not of local legislative bodies, but of the US Congress 500 miles away.

Until very recently, TVA has been held in such affection by most residents of the Tennessee Valley—particularly those with long memories—that the remoteness of the control over the agency has been no problem. But recent sharp increases in TVA's electricity rates in response to escalating coal prices have caused some alienation and frustration because there's no local body to which complaints can be addressed. The frustration was voiced on several occasions during last year's Senate hearings on TVA, the most provocative comment being the reference to colonialism, but few suggestions for improving the situation were voiced.

Nevertheless, to most of the people in the region, TVA remains an instrument for economic progress. Certainly, few would deny that it has more than lived up to Roosevelt's hopes that it would reclaim the Tennessee Valley's land and people. ☐

US SPACE

Biological business boom

Sandy Grimwade reports from Washington on the progress of the Viking 1 experiments on Mars

AFTER more than five weeks of practically faultless operation the Viking 1 Mars lander continues to send a wealth of geological, meteorological, biological, chemical and visual information back to Earth. The only instrument which has failed to function correctly is a set of miniature seismometers which remains locked in the safe landing position, despite efforts to free it. The other teams of scientists have, however, been kept busy by the sheer volume of information being supplied to them.

Some of the most puzzling and to the general public most fascinating data have come from the three biology experiments and the related molecular analysis of the Martian soil. Although control and duplicate experiments—the *sine qua non* of all biological investigation—have not yet been done, speculation is rife as to the meaning of the results so far. The scientists involved are understandably cautious about delivering a yes–no answer to the question of life on Mars, when only a small portion of their programme is complete. The results so far are certainly not what would be expected if Earth-type organisms were present, nor are they explicable in terms of "simple" non-biological chemistry.

In the labelled release (LR) experiment, a mixture of ^{14}C-labelled nutrients in a small amount of water was added to a soil sample and incubated at about 15 °C, which is 35–135 °C warmer than the Martian surface temperature. The totally unexpected result showed a massive and rapid release of radioactivity into the gas phase—presumably as carbon monoxide or dioxide. The radioactive counts released reached 4,500 in 10 hours, levelling off after 48 hours at about 8,500. A second dose of radioactive nutrients caused an initial burst followed by a drop in the released radioactivity, after which the graph almost flattened out for the remaining four days of the experiment.

That "almost" is the tantalising part, because careful statistical analysis revealed a possible trend of very slow accelerating release of radioactivity. Unfortunately, the exigencies of operating one's laboratory by remote control across 200 million miles required the experiment to be stopped for performance of a control test with heat-sterilised soil. A later repetition of the experiment is planned with an incubation time of weeks or months rather than days. The results certainly do not look like anything one would expect from an Earth sample in the same situation. A chemical explanation involving oxidation of the labelled nutrients is at present the most popular explanation for the initial burst of activity.

The possibility that the Martian soil contains active oxidising agents was strengthened by the result from the gas exchange (GE) experiment. In this experiment the soil sample is either humidified or wetted with a concentrated "chicken soup" of amino acids, salts, vitamins and other nutrients, and the atmosphere is periodically monitored for changes in the concentration of gases by gas chromatography. The initial humidifying of the soil sample produced a remarkable release of oxygen which levelled off after several hours and remained stable for days. Wetting of the soil caused a rapid drop in the atmospheric CO_2, probably due to the formation of bicarbonate in the alkaline solution, and a slower drop in the oxygen, which is speculated to be due to oxidation of ascorbic acid which is present in the nutrients. At present, CO_2 is slowly being released into the atmosphere and the experiment is intended to continue for some time to see if any further changes occur. As the instrument is capable of detecting very small changes in hydrogen, methane, nitrogen and other gases, a wide range of possible biological activities could be detected.

The results of the GE and LR experiments are open to several more or less imaginative interpretations, and attempts are at present being made to duplicate the results in several Earth laboratories using simple catalysts and oxidising agents. The third experiment, the pyrolytic release experiment (PR), although perhaps the most complex technologically, is also the least equivocal when it comes to interpretation of the results. It is designed to detect the fixation of labelled carbon monoxide and dioxide in organic compounds. A sample of soil is incubated in a Martian atmosphere with added water vapour and irradiated with a simulated sunlight xenon lamp. After five days the sample is heated to 625 °C to pyrolyse organic compounds which are trapped as vapours, and to drive off unreacted CO and CO_2. This unreacted gas is passed through a radioactivity detector and forms the first "non-biological" peak. The organic vapour trap is then heated to 700 °C to release and oxidise

Photo: NASA

Martian dune field

the remaining organic compounds which form the second, "biological" peak.

With a sterile sample a peak ratio of about 500 to 1 would be expected. The result from the Martian soil was about 75 to 1 due to the high "biological" peak. This is several times more active than non-sterilised soils from the dry valleys of Antarctica. The result from the control experiment with heat-sterilised soil is crucial in this instance, a high peak ratio indicating the possibility that biological rather than chemical processes capable of fixing atmospheric carbon monoxide or dioxide in the presence of light are taking place in the soil. If life exists on Mars, this is what might be expected in the soil surface which is strongly illuminated and bathed in an atmosphere of about 95% carbon dioxide. The biologists would be even more encouraged if organic compounds were detected in the Martian soil.

Unfortunately, the initial run of the organic chemistry analysis was less than satisfactory due to the temperamental soil sampling boom which apparently failed to deliver a full load of soil to the gas chromatograph-mass spectrometer. No organic compounds were detected. A full soil load has now been obtained and a further analysis is being carried out. If organic compounds are not detected this would be a blow, though not a fatal one, to the concept of life on Mars, and would render interpretation of the three biology experiments more difficult. □

USSR SPACE

Forward with the programme

Vera Rich reports on the latest Soviet space missions

> "Soviet science considers the creation of orbital space stations with interchangeable crews as the main highway of mankind into space. They can form 'cosmodromes in space', launch pads for flights to other planets. Large-scale scientific laboratories will arise for the investigation of space technology and biology, medicine and geophysics, astronomy and astrophysics."

So said Mr Brezhnev in a recent statement. The idea was by no means new; it is a fundamental tenet of all Tsiolkovskii's work that such a station would and must precede manned exploration of the moon and planets. There are, indeed, some indications that Soviet space planners have at times been prepared to consider the alternative of manned exploration direct from earth—the argument that a lunokhod-carrying automatic spacecraft could carry out its survey work at "half the cost" of a manned mission, for example, suggests that the latter possibility had at least reached the costing stage. Now, the flight of the unmanned Luna 24 has repeated the task of Luna 16 by obtaining and returning with a sample of moon-rock, though from a depth of two metres and from *Mare crisium*, from which no samples had yet been obtained. Presumably present space plans still do not envisage cosmonauts venturing beyond earth orbit.

Whatever the overall timetable of the Soviet Union's space plan, though, many of the experiments now being conducted by the 7-week-old Salyut 5 mission suggest that the concept of a permanently manned space station is still well to the fore. These latter experiments fall into three main groups: geophysical and astrophysical observations, technological experiments and biological experiments. Of the technological experiments, some are directly concerned with processes and techniques which would be required in the construction of a space station—notably the study of the behaviour of gases in liquids in space and, of some importance, a soldering experiment. Unlike the welding experiments of an earlier mission, the soldering, which uses a highly exothermal chemical reaction to produce the necessary heat, is aimed less at testing the cosmonaut's dexterity than at investigating the process itself. The welded metal specimens are to be returned to earth for further investigation of their structure.

The emphasis has clearly shifted to the properties of materials treated under conditions of weightlessness. Other experiments include the growing of crystals (also to be returned to earth), and the cooling of molten metals—bismuth, lead, tin and cadmium—to determine surface tension. These experiments will, of course, provide data of considerable theoretical significance: crystals grown under weightlessness, for example, should be free of convection-induced defects, and should, it is hoped, provide valuable comparative data for crystallographers and geologists. It is significant, however, that all these experiments are described in the official announcements as "technological", suggesting that their practical importance should not be minimised.

The medical problems of prolonged spaceflight are also receiving considerable attention. Apart from such obvious parameters as muscle tone, cardiovascular and respiratory performance, and loss of body weight—measured on the special "massometer"—the medical programme includes special monitoring of the cosmonauts in a "vertical" position (however that is to be interpreted), tests on reaction time in performing complex operations and manual control (real or simulated) of the spacecraft (the simulated control presumably relates to possible emergencies), and even possible variations in taste.

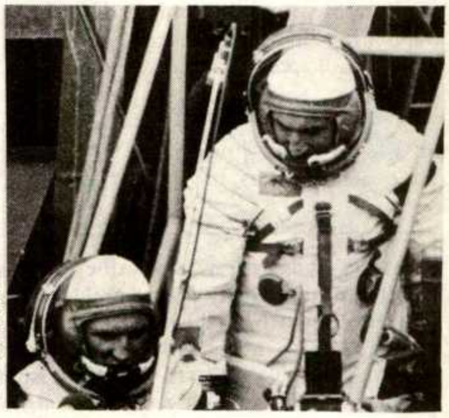


Photo: Novosti

Before blast-off for Salyut 5

Press comment on the medical programme suggests a growing concern over the psychological effects of prolonged spaceflight. These would arise from a lack of external stimuli, the restriction of living space and general monotony—an aspect of spaceflight which will assume ever greater importance in future missions when the length of flight and the crew size increases. Aboard Salyut 5 are such simple prophylactics as recorded music (from folk to classical) and a varying make-up of the ration-packs.

Commenting on the radiation safety system used aboard the Salyut craft, Ludvig Palmbakh of the USSR Institute of General Genetics stated that the protective measures used are "well adapted" for work near Earth, since, if solar radiation rises to danger level, the crew can be quickly evacuated and brought back. For deep-space missions, however, "more active" means of protection would probably be required, possibly involving the deflection of high-energy particles by electromagnetic fields. The design of such systems entails considerable technical difficulty, so the fullest possible information is required both on the nature of the radiation and the actual hazard involved. The cytological and genetic experiments, using drosophila and hawksbeard, carried by Salyut 5, should provide further data on these hazards. □

IN BRIEF

Seabed hearings

The dispute between Greece and Turkey over the Aegean seabed is due to receive a hearing at the International Court of Justice at The Hague this week. Greece is seeking to prevent the Turkish oceanographic research ship *Sismik I* from continuing its oil exploration, and wants a ruling on the limits of the continental shelf. In New York at the latest round of the Law of the Sea Conference, meanwhile, Dr Kissinger is reportedly threatening unilateral action by the US over exploitation of deep-sea minerals, on the regulation of which the conference has been deadlocked.

Pesticide dumping

In what Federal prosecutors in the US have described as the largest environmental case ever brought, the Allied Chemical Corporation last week pleaded *nolo contendere* on 940 counts connected with the dumping of the pesticide Kepone in the James River. Fish in the river and in Lower Chesapeake Bay (where an Allied Chemical barge containing 250,000 tons of sulphuric acid capsized last week) were found to contain Kepone. The corporation could now face fines of about $13 million.

Coal gasification 'option'

On the basis of a report it published last week, the UK National Coal Board (NCB) has decided not to resume, at least for the moment, applied research into underground coal gasification—the direct extraction of gases from coal seams burnt underground. The NCB identifies underground gasification as a realistic energy option, however, and will continue monitoring international research efforts until costs—now put at 7–24 pence a therm—can be reduced to something nearer those associated with conventional mining techniques.

Cooperation in an international pilot scheme costing £10–15 millions could, the NCB feels, become worthwhile within five years or so. Outstanding problems of underground gasification include the poor quality of the gases produced, the lack of control over supplies, and the danger of seepage to the surface or into mineshafts and groundwater. During the 1950s Britain was among the pioneers of underground gasification research, which is now led by Belgium, Canada, the USA and West Germany. The Soviet Union operates a small-scale commercial facility.

Wildcat story

THOMAS H. JUKES

YEARS ago, as a young father, I was often asked by my infant children for a bedtime story. On one such occasion, I gave a partially true account of a camping trip to a lonely spot where I was suddenly confronted, at dusk, by a ferocious animal, yellow-eyed and snarling. It was a wildcat! At this point in the narrative, the children screamed and hid beneath the covers. Soon they were sleeping soundly. Next evening, I asked what they wanted to hear in the way of a soporific monologue. The answer, to my surprise, was: *The Wildcat Story*. It was a best-seller for weeks. People love tales that make their flesh creep.

As time went by, I recognised many versions of the wildcat story in scientific writings. Whether or not these are true, their common property is that they are entrancing because they are "scary". One of the most fascinating is the recombinant DNA story. My grandchildren are too ecologically sophisticated to be terrified by wildcats. Perhaps I can startle them with an imaginary account of meeting up with a genetically-engineered *E. coli* cell.

According to a recent news report, many inhabitants of Cambridge, Massachusetts, are greatly worried by the possibility that "hot" *E. coli* cultures might escape into the sewers, nowadays called "the environment". Carelessness in the laboratories of Harvard University and the Massachusetts Institute of Techonology was named as a cause that might lead to this disaster, which could be accentuated by the decrepitude of the facilities at Harvard. It was said that George Wald has explained the danger to the Mayor of Cambridge, Massachusetts, Mr Vellucci, who has been an advocate of converting Harvard Yard into a parking lot. The mayor was apparently a ready listener, this being a rare case of a progressive public official giving ear to erudite eloquence. Perhaps, with the Mayor's attention diverted by colon bacilli, Harvard Yard may be saved.

The incident is somehow typical of a shift in attitudes towards scientific discoveries. Once we were eager to try new things, and none would say us nay. Today, dangers are recognised even before they have been shown to exist. If penicillin had been discovered in the 1970s instead of the 1930s, it would probably have been kept out of the hospitals after preliminary tests had shown it to be potentially allergenic, and the testers had been sued for medical malpractice.

Somehow I have a feeling that anything *E. coli* could do to us has already been done during the millions of years that this organism has lived in countless numbers within the intestinal tracts of vertebrates. It has a set of genes that code for transfer RNA molecules. But these molecules have different base sequences from those in human tRNAs, although both sets of tRNAs function similarly. The differences indicate that the sets have evolved separately for hundreds of millions of years. Why has there been no mixing? Are all the transformations phenotypic? Would the new, human-tailored bugs take over the sewers? Or would they stand about as much chance as a hothouse orchid in a patch of good healthy ragweeds?

If Mr Vellucci prevails, we are not likely to find out. I would be a bit peeved if I were a young bacteriologist, being held back by the old guard who have made it to the top. However, many young scientists seem quite satisfied to join, or even to excel, the elderly prophets of doom.

Now that Viking has landed, we can brace ourselves for an airing of the greatest of all wildcat stories. It seems that a capsule of unsterilized Martian soil came back to Earth, swarming with weird organisms that gobbled up atmospheric nitrogen. The first news we heard was that millions of people were dying east of the Urals. . . .

news and views

Concentration factors and radiological protection

from Pamela M. Bryant

THE behaviour of plutonium in the environment is of topical interest especially in view of proposals in several countries of the world to embark on power programmes involving the use of fast breeder reactors. Knowledge is currently expanding as a result of studies on plutonium present in the environment from nuclear weapons tests and disposal of wastes from nuclear fuel reprocessing plants From a knowledge of the levels of plutonium activity in relevant environmental materials it is possible to estimate the associated radiation exposure of humans. When that knowledge is sufficiently broad to quantify the behaviour of plutonium in inter-related environmental materials, it is possible to predict the approximate level of radiation exposure of humans corresponding to the postulated additions of plutonium to the environment.

In a paper in this issue of *Nature* (page 745) reporting the results of measurements of plutonium concentrations in the water of Kwajalein lagoon in the Marshall Islands, Noshkin *et al.* examine published data on plutonium concentrations in water and fish from nearby and distant locations. This examination leads the authors to conclude that all the available data on plutonium in fish are seemingly inconsistent and that, if the available Enewetak and Kwajalein data are correct, the availability to all fish and invertebrates of plutonium, from whatever source, depends more upon the type of environment than on plutonium levels in that environment. They state that such a conclusion would greatly affect future plans for discharging low activity transuranic wastes to the marine environment. They also say that it would force them to concede that the concept of a plutonium concentration factor for fish (the ratio of the concentration of plutonium in fish to its concentration in the surrounding water) is meaningless.

In a preliminary report on levels of plutonium isotopes and ^{241}Am in various tissues in plaice from the north-eastern Irish Sea, Pentreath and Lovett (this issue of *Nature*, page 814) include data on discharges of these nuclides from the nuclear fuel reprocessing plant at Windscale, Cumbria. Plaice is a fish of commercial importance in the area; it is monitored regularly, as part of the established control procedure of the Ministry of Agriculture, Fisheries and Food (MAFF), primarily to ensure the radiological safety of the discharges in public health terms. Pentreath and Lovett comment that in view of the fluctuating discharges a steady-state burden will not exist for fish caught close to the pipeline; thus, an accurate estimate of the concentration factor between fish and seawater cannot be made. The concentration factor would, in any case, depend on the location of the seawater sample and the movement of the local population of plaice.

Yet another complication in the estimation of concentration factors is evident from recent reports which suggest a preferential biological availability of ^{238}Pu over ^{239,240}Pu in terrestrial and aquatic organisms. The reports were noted with interest by Beasley and Fowler (page 813 of this issue of *Nature*) in a paper describing plutonium isotope ratios in polychaete worms. These authors found that these deposit-feeding marine worms, living in sediments contaminated with plutonium isotopes from a variety of sources, did not preferentially accumulate ^{238}Pu over ^{239,240}Pu. They conclude that until the reasons for the disparities become clear general statements regarding preferential biological availability of ^{238}Pu over ^{239,240}Pu should be viewed cautiously

The limitations of values for concentration factors between water or sediments and marine organisms are well recognised by persons using them for prediction purposes in the field or radiological protection and carrying out research programmes connected with control procedures for waste discharges

A basic policy applied to the control of radioactive discharges to the marine environment from nuclear establishments in the United Kingdom is that the government departments responsible authorise discharges at levels below those which correspond by calculation to the dose limits for the general public recommended by the International Commission on Radiological Protection (ICRP) The authorised limits are set on the basis of the need to do what is reasonably practicable, having regard to cost, convenience and the national importance of the subject, to reduce doses far below the ICRP dose limits. The environmental consequences of such discharges of radioactivity are also borne in mind, although it is generally found that the public health considerations are more limiting than considerations relating to environmental resources.

The first stage in determining discharge levels corresponding to ICRP dose limits, for example when a new discharge is being considered, involves modelling of the environmental pathways likely to be of greatest importance. Such modelling seeks to estimate the long-term average level of radiation exposure, under steady-state conditions, corresponding to the postulated disposal practice. Where an element of doubt exists, pessimistic values of concentration factors are used. In the early stage of an operation, discharge of no more than a small fraction of the level indicated by this modelling is permitted; at this stage research additional to control monitoring is undertaken to check the predicted relationships.

In the particular case of plutonium discharges from Windscale, monitoring is carried out by the MAFF Fisheries Radiobiological Laboratory of materials which include the important elements of human food chains such as fish, shellfish and the edible seaweed *Porphyra umbilicalis*; as well as seawater and sediment whose role as a "sink" for plutonium introduced into the sea is well recognised. The object of this study is to answer some of the questions posed by the introduction of a long-lived radionuclide into the marine environment. The expected results of this study include improved understanding of the concentration factors between environmental materials in the region and their limitations. Control of public health, however, is exercised by the direct measurement of radioactivity in those environmental materials responsible for human exposure; in the case of actinides discharged from Windscale the most important measurements concern plutonium and americium in the edible fraction of Irish Sea plaice taken from the sea area most liable to contamination. It is difficult to understand, therefore, why the uncertainty as to the validity of the concept of concentration factors for fish expressed by Noshkin *et al.* should lead to their conclusion that future plans for discharging low activity transuranic wastes to the marine environment would be affected.

Enkephalin: the latest instalment

from Leslie Iversen and Raymond Dingledine

> The 5th International Narcotic Research Conference was held in Aberdeen on July 19–22, 1976. The full proceedings of the meeting will be published by North-Holland in September under the title *Opiates and Endogenous Opioid Peptides.*

THE central effects of morphine and opiate-like drugs have been known for thousands of years, but only in the past five years has real progress been made in understanding the actions of these drugs on the brain, or the significance of the existence of specific opiate receptors in normal brain function. The first catalytic breakthrough was the discovery by Pert and Snyder[1] of a simple, sensitive assay for brain opiate receptors. Equally exciting was the report by Hughes *et al.* last December[2] of the identification of two naturally occurring pentapeptides in brain—the enkephalins—whose properties mimic those of morphine, and this was the focus of attention at the recent meeting in Aberdeen.

Although the identification of the enkephalins has since been confirmed[3], it has also become apparent that there are several other, larger, naturally-occurring peptides that share similar pharmacological properties. Most of these peptides, now known generically as the "endorphins", derive from the 91-amino acid pituitary peptide β-lipotropin. Thus several groups have now reported that a pituitary peptide corresponding to the C-terminal portion of β-lipotropin (residues 61–91, known as C-fragment of lipotropin or β-endorphin) has morphine-like properties in various test systems[4–6]. Similar properties are exhibited by other naturally occurring fragments of β-lipotropin, for example the C'-fragment (residues 61–87, also known as γ-endorphin) and α-endorphin (residues 61–76)[7]. Met-enkephalin (Tyr-Gly-Gly-Phe-Met) consists of residues 61–65 of β-lipotropin, and all of the above peptides share this common sequence at their N-terminal region. However, Leu-enkephalin (Tyr-Gly-Gly-Phe-Leu) does not seem to be derived from β-lipotropin, and there may be yet more morphine-like peptides still to be characterised. A. Goldstein (Stanford University) reported at the meeting that it seems unlikely that the β-lipotropin derived peptides can account for all of the opioid material extractable from pituitaries, and A. Wahlström (University of Uppsala) reported on an opioid peptide from human cerebrospinal fluid that appears to be chemically different from all known fragments of β-lipotropin. In addition, C. Pert (National Institute of Mental Health) reported that normal human blood contains a low molecular weight opioid, named "anodynin", which is not an enkephalin[8]. The anodynin content of rat blood was abolished after hypophysectomy, strongly suggesting pituitary origin.

All this is, to say the least, a little confusing. Are the pentapeptides in brain really the naturally occurring morphine-like substances? Should one perhaps regard the pituitary peptides and brain enkephalins as belonging to completely different functional systems; or could the enkephalins merely represent breakdown products of the larger peptides? If so, it would be a unique situation among peptide hormones for their precursor molecules to exhibit strong physiological activity, since the larger endorphins seem to be more potent than the enkephalins in most test systems. The enkephalins are, however, rapidly destroyed by peptidases in brain and other tissues[9], and the metabolic stability of the larger endorphins may account for their dramatic and prolonged pharmacological actions. In support of this A. Pert (National Institute of Mental Health) reported that the simple chemical derivative D-Ala^2-Met-enkephalinamide, which has half the affinity for the opiate receptor of Met-enkephalin but is resistant to enzymatic degradation, produced powerful long-lasting analgesia in rats when injected into the brain. Other synthetic analogues of the enkephalins that are metabolically stable were reported by D. Smyth (National Institute for Medical Research, Mill Hill), and they seem likely to become useful research tools.

A disappointing finding for interested clinicians was that prolonged treatment with the endorphins seems to induce tolerance and dependence, just like other opiates. The clearest evidence for this came from E. Wei (University of California), who reported that following the chronic infusion of very small amounts of β-endorphin or Met-enkephalin into the brain (using an ingenious implanted osmotic mini-pump), rats exhibited typical withdrawal signs when challenged with naloxone (see also ref. 10).

Further progress in identifying central sites for the analgesic effect of opiates was provided by H. Takagi (Kyoto University), who reported that microinjection of morphine into the nucleus reticularis gigantocellularis resulted in naloxone-sensitive analgesia and mimicked the inhibitory effect of systemic morphine administration on spinal lamina V cells. H. Akil (Stanford University) demonstrated that endorphin levels in rat brain rise during a stress-induced analgesic state, and postulated that environmental situations that activate the endogenous pain-inhibitory system[11] may involve the opioid peptides. Of potential importance also is the recent finding by Simantov and Snyder[12] that enkephalin levels are increased in the brains of morphine-tolerant rats.

Many speakers described the close similarity between the actions of morphine and the endorphins in brain and peripheral targets. Thus the endorphins produce a naloxone-sensitive analgesia when injected into the brain (see also refs 13 and 14), have characteristic morphine-like actions on the guinea pig myenteric plexus and mouse vas deferens preparations, and display other behavioural opiate-like effects such as catatonia in rats and locomotor activity in mice. In addition, all the endorphins displayed a respectable affinity for binding to opiate receptors, but here some curious anomalies were described. N. Birdsall (National Institute for Medical Research) showed that the displacement by morphine or Met-enkephalin of a radiolabelled opiate agonist followed different kinetics from their displacement of labelled antagonists (see also refs 15 and 16). Met-enkephalin was less effective in competing for binding sites for labelled naloxone than in competing for its own binding sites in brain, and morphine was much less potent in competing for labelled enkephalin binding sites than in displacing ^{3}H-opiates. These differences might be explained by multiple receptor conformations[17], but H. Kosterlitz (University of Aberdeen) proposed the existence of a family of opiate receptors, on the basis of the binding anomalies and variations in rank order of potency for a series of opiates when tested in different peripheral assays.

In terms of cellular responses it was clear that the enkephalins closely mimic morphine. Thus, B. Hamprecht (Max-Planck-Institut für Biochemie, Martinsried) found that very low concentrations of enkephalin stimulate cyclic GMP formation in cultures of neuroblastoma × glioma cells, and W. Klee (National Institute of Mental Health) that enkephalins inhibit basal and prostaglandin-stimulated cyclic AMP formation in the same cells (see also refs 18 and 19). K. Minneman (University of Cambridge) reported a similar stimulation of cyclic GMP formation by morphine and the enkephalins in slices of rat striatum, although high concentrations of the peptides were needed because of their metabolic instability[20]. Several groups have studied the responses of single neurones in different brain regions to iontophoretically applied enkephalin, and in general these peptides mimic the inhibitory actions of morphine[21–24], although specific excitatory actions have been observed on Renshaw cells[25]. Intracellular records from spinal interneurones and motoneurones by W. Zieglgansberger (Max-Planck-Institut für Psychiatrie, Munich) suggested that the inhibitory effect of morphine and enkephalin may be due to blockade of ionic conductance at chemically excitable Na$^+$ channels, an hypothesis similar to that of Snyder's group[17]. Intracellular recordings from morphine-sensitive neurones in the myenteric plexus by R. North (Loyola University) however, showed that at this peripheral site opiates may hyperpolarise cells by causing an increase in membrane conductance.

Several other new pieces of information relevant to understanding the possible physiological function of the endorphins were presented. R Simantov (Johns Hopkins University) and J. Hughes (University of Aberdeen) found that the regional distribution of enkephalin in brain is similar to that of the opiate receptor itself: with high levels, for example, in corpus striatum and hypothalamus and negligible amounts in the cerebellum. Hughes also described a calcium-sensitive release of enkephalin-like material from brain synaptosome preparations in response to depolarising concentrations of potassium. Progress in discovering possible "endorphinergic" synapses will be aided by two other technical developments: the autoradiographic mapping of the anatomical distribution of opiate receptors (reported on by M. Kuhar, Johns Hopkins University), and the mapping of possible endorphin-containing neuronal pathways in the brain by immunohistochemistry. The latter method has recently been successfully applied by T. Hokfelt and reported at the Collegium Internationale Psychopharmacologium meeting in Quebec last month. Further instalments of this bulletin may be expected before long!

Farmington: an Apollo meteorite

from David W. Hughes

FARMINGTON Township, Washington County, Kansas, is famous, at least to meteoritisists, as the place where an L5 chondrite fell to ground in June, 1890. The meteorite itself is famous because it has a uniquely short cosmic-ray exposure (or "radiation") age, having left its parent body a mere 25,000 years ago. This latter fact is most significant because it means that the orbit the meteorite had as it intersected the Earth was its original orbit, the one it obtained immediately after release from its parent body. This orbit therefore gives a direct clue to its place of origin.

Meteorite ages are obtained by looking at the accumulated spallation products and nuclear tracks produced in the body of the meteorite due to the penetration of galactic cosmic rays. This irradiation usually begins as soon as the meteorite is ejected from its parent body, so the radiation age equals the transit time between that body and Earth. On average this is 10^7 years. Now every time a meteorite passes close to a planet its orbit changes, and a pass as far away as 10 planetary radii will alter the direction of motion of the meteorite by a few degrees. Opik (*Adv. Astron. Astrophys.*, **4**, 301; 1966) calculated that this happens about every 5×10^5 yr so Farmington, which had had a separate existence in the Solar System for a twentieth of this time, was most probably on its pristine, unaltered orbit. This would differ slightly from the orbit of the parent body because of the random velocity given to Farmington on ejection but as this velocity is generally less than a few hundred metres per second the change is only marginal. So with Farmington (and Farmington alone, as other meteorites have been in the Solar System much longer and have greatly altered orbits) there is a real chance of finding out exactly where it came from. To do this its orbit has to be calculated and Boris Levin and Alla Simonenko (Academy of Sciences of the USSR, Moscow) and Edward Anders (University of Chicago) have done just this in a recent paper in *Icarus* (**28**, 307; 1976).

They enlisted the help of the Kansas and Nebraska Historical Societies who diligently went through 280 different newspapers from 91 counties published around June, 1890, looking for reports of the fall. Thousands of people over a 300×300 km area saw the bolide and 144 news items appeared in the press. There were many vivid descriptions: "a bright meteor passed swiftly to the north-west and burst into glittering fragments high in the air"; "it was a ball of fire as large as a table. It had a trail like a comet and it wobbled like a kite"; "its path could be discerned by the smoke that followed it". To some it sounded like the firing of a cannon, to others it had a "long rumbling rolling noise like thunder". Close to the impact point the ground shook just as in an earthquake. The most startled person was a Mr J. H. January who was "breaking the prairie sod" when the 85 kg meteorite fell almost vertically some 150 m in front of him and made a hole with nearly vertical sides.

None of these descriptions of the Farmington bolide contains any quantitative data on the azimuths and angular heights of the beginning and end points of the fireball. But near the point of fall anyone seeing the meteorite would be looking along the trajectory and the fireball would appear to be stationary and in the direction of the apparent radiant. Just such an effect was observed from Washington, Kansas, 7.1 km south of Farmington where the meteorite was also seen to be just below the Sun. The explosion and extinction happened after the passage over Washington, at an end height of about 10 km. The zig-zag course reported by some people near Washington was due to a physiological effect. The eye can only follow a moving object if its angular velocity is less than 30° s^{-1}. At greater velocities the eye pursues the object in jumps (the so-called saccadial movement). As this jumping was seen, the object must have been moving at about 5 km s^{-1} or somewhat slower.

Combining all the observations, Levin, Simonenko and Anders conclude that the apparent radiant was 20° west of south at an azimuth of 60°, giving Farmington a very steep trajectory through the atmosphere. The beginning and end heights were very similar to the Příbram and Lost City meteorites (98, 87 km and 13, 17 km respectively), the only other two meteorites to have known orbits (these being obtained from photographs taken from networks of cameras). The pre-atmospheric velocity must have been in the range 11.3 to 22 km s^{-1}. The lower bound is the Earth's escape velocity, the upper one being due to the fact that meteors moving faster than 22 km s^{-1} suffer complete ablative destruction. Using velocities in this range and the apparent radiant position obtained from the eyewitness reports the authors calculate a set of pre-collision orbits for the meteorite. They find that the meteorite struck the Earth at the ascending node of its orbit ($\Omega=275°$) and that the orbit had a small semi-major axis (between 1 and 1.3 a.u.) and a low inclination (5 to 10°). The eccentricity was around 0.21 and the argument of perihelion between 240 and 270°. The aphelion was at 3.0 a.u., in the densest part of the asteroid belt, and the perihelion could not have been less than 0.4 a.u. (interestingly chemical analysis showed that ^{3}He and ^{4}He had not been lost by the meteorite during its lifetime supporting the argument against a small perihelion). Fortunately all these results are insensitive to errors in the apparent radiant.

The facts point towards Farmington being a fragment from the collision between an Apollo asteroid and some other meteorite or asteroid. The Apollos are a short lifetime (10^7–10^8 yr) group of asteroids which have Earth-crossing orbits. They are thought by some to be too rare to provide all the stony meteorites. If they do, then the undiscovered Apollos should exceed the known Apollos by one or two orders of magnitude.

Of the 11 known Earth-crossing asteroids with encounter velocities below 22 km s^{-1}, Hermes, 1862 Apollo and 1865 Cerberus have orbits which fall within the error limits of the Farmington orbital elements, however none can be singled out definitely as the parent body. The uranium–helium age of Farmington is 5.5×10^8 yr (Heymann, *Icarus*, **6**, 189; 1967) indicating that it was reheated extensively, as were all L chondrites, in the collision that broke up the parent body. This collision must have involved an unusually large projectile which deposited more energy per unit mass than a typical cratering event. The remnants of the body could comprise a highly fragmented Hirayama or Flora family with a steep mass distribution.

So amidst a plethora of theories concerning asteroidal origin Farmington's place of birth seems to be known and was most probably an Apollo asteroid, this fact coming to us by courtesy of the careful scrutinising of the 1890 files of such worthy papers as the *Atchison Patriot*, the Omaha *Daily Bee* and the Wymore *Weekly Wymorian*.

EMBO ribosome workshop

from Richard Brimacombe

The fifth EMBO workshop on ribosomes took place in Brussels from August 2–6, 1976 under the organisation of Dr Alex Bollen of the Université Libre de Bruxelles.

THE ever-increasing complexity of ribosomology was reflected in the large number of participants (about 150), but the meeting was also characterised by a notable change of emphasis in the range of topics discussed, which was largely a result of the increasing contribution of chemical and physicochemical studies to the subject, at least in the case of prokaryotes. Progress over the past two years was summarised in the opening lecture by the organiser of the previous EMBO meeting (C. G. Kurland, Uppsala University), who laid particular stress on the developments in physical chemistry, which has become not only concerned with the structural aspects of the ribosome problem, but is also beginning to be concerned with the question of the specificity of the translation process in terms of kinetics.

One of the physicochemical methods now being used successfully to investigate ribosome structure is neutron scattering; results obtained with this technique were presented by P. Moore (Yale University), who, by making reconstituted ribosomes containing two deuterated proteins, has been able to estimate the distances between centres of mass of a number of pairs of proteins within the *E coli* 30S subunit The technique also indicates that many proteins are far from spherical in shape. Neutron scattering gives information about the overall shape and size of the subunits, and has been used in addition to probe the distribution of RNA and protein within the subunits; it seems that the central cores of the subunits are rich in RNA, particularly in the case of the 50S, whereas the surface regions are richer in protein (M. Koch, University of Louvain).

The neutron data are not yet sufficiently advanced to be compared in detail with the data from another very topical technique—the direct electron-microscopic demonstration of protein-specific antibodies bound to the ribosome surface. This method has produced two models of the *E. coli* ribosomal subunits, one of which was presented by G. Stöffler (Berlin) and the other by J. Lake (University of California, Los Angeles). Both protagonists arrived armed with an impressive array of hideously-coloured plastic ribosomal sculpture, and there was some lively discussion of the differences between the two models, which rather tended to obscure the fact that despite these differences there is substantial agreement, with regard both to the overall shapes of the subunits and to the details of the protein arrangement. In particular, there can now be no doubt that many proteins have very irregular and elongated shapes within the ribosome.

Physical chemistry is now being applied to the kinetics of the translation process. Ten years ago the question of codon–anticodon recognition did not seem to be a problem, but now it is by no means simple when considered in detail (J. Ninio, Paris; H. Grosjean, Brussels). The crux of the matter seems to be the degree of "stickiness" of the interaction between a codon and a potential anticodon; the correct anticodon will have a longer sticking time, and thus more chance of leading to amino acid incorporation, than an incorrect anticodon. The ribosome therefore needs to have time to make up its mind what to incorporate, an idea supported by some results from A. Spirin (Poustchino), who showed that stimulation of the rate of the translocation process by addition of

Mercury's magnetic field

THE origin of Mercury's magnetic field has recently become a subject of considerable research interest. Still debatable is whether the dipolar field (less than a thousandth of that on Earth) comes from a currently active dynamo or is a relic of earlier fields (or, of course, is some combination of these). We wish to take up some of Peter Smith's points in an earlier *News and Views* article (*Nature*, **260**, 578; 1976) on this subject.

If the field observed comes from remanent magnetisation only, the first question that has to be decided is down to what depth this magnetisation exists. Mercury's core, if not generating a magnetic field, would probably still be above the Curie point (Solomon, *Icarus* (in the press)), so it is reasonable to think only of a shell of material with modest magnetic susceptibility. Goldstein (*Nature*, **258**, 175; 1975) showed that a dipole moment results, in general, in such a shell after it has been magnetised in the field of an internal, now extinct, dipole. Stephenson, in a quantitative analysis of the problem (*Earth planet. Sci. Lett.*, **28**, 454; 1976) obtained an ancient surface polar field of less than 10 Oe only if the volume percentage of iron in rocks of a 243 km-thick mantle were 5%—more than a hundred times the typical value in lunar basalts. No support for such an anomalously high iron content comes from the Mariner 10 photometric observations (Hapke, *et al.*, *J. geophys. Res.*, **80**, 2431; 1975). Srnka has recently carried out a similar, though more detailed calculation (*EØS*, **57**, 271; 1975), from which he concludes that an ancient surface field of about 16 Oe was required along with a volume percentage of iron of about 3.0%. We currently believe that on the basis of this work, the remanent magnetisation hypothesis for the field is not a likely one.

We admit that these calculations could be significantly modified; Solomon, for instance has pointed out that if the segregation of metals from silicates is incomplete in the mantle and crust of Mercury, the resulting increased thermal conductivity could lead to a thicker shell below the Curie temperature, somewhat reducing the required magnitude of the ancient magnetising field. Furthermore, if the iron content were as high as Stephenson assumes, then ferromagnetic effects might dominate.

There are, on the other hand, additional difficulties for remanent magnetisation models; among them is the observation of Murray *et al.* (*J. geophys. Res*, **80**, 2508; 1975) and others, that craters such as the Caloris basin must have modified the planetary structure to depths greater than 100–200 km, approximately the thickness of the shell in which remanent magnetisation would be acquired. Cratering could thus severely disrupt any extant magnetisation pattern (Wasilewski, *Moon*, **9**, 335; 1974).

The other major alternative is a currently active dynamo for which a necessary but not sufficient requirement is a molten core—what evidence do we have for this? Solomon and others have pointed out that cosmochemical models not including a substantial heat source predict core solidification within about 1 billion years after infall. That would result in a contraction of Mercury's radius of some 18 km (Solomon, *op cit.*), which is not observed—indirect evidence that a molten core may exist. Proposals for heat sources include the retention of some U and Th in the core after differentiation; the presence of about 156 p.p.b. ^{40}K; presence of elements such as S in the core, which would lower the solidus temperature; and models which distribute the gravitational heating over more of the planet's history.

Finally, there is the remote possibility that the field of Mercury is due to remanent magnetism from an external source field. Sharpe and Strangway (*Geophys. Res. Lett.*, **3**, 285; 1976) propose a cool model in which a 100 km shell of a few per cent iron cools rapidly below 800 °C in a field of some 10 Oe. In their calculation, they suggest that if Mercury accreted cold (at about 300 K; as opposed to 1,200 K which is usually used as the base temperature) the present-day field could result from fossil remanent magnetisation retained in the inner half of the planet.

Peale, in this week's *Nature* (page 765), proposes an experiment which would contribute to a solution of the origin question. The dynamical behaviour of Mercury will be slightly affected by the existence of a liquid core; measurements of the amplitude of libration in longitude, the obliquity to the ecliptic and two functions of moments of inertia should suffice. None of these measurements would be easy—the last two would require tracking of artificial satellites, the first two would require the establishment of some form of astronomical observatory on Mercury.

The origin of Mercury's magnetic field will probably not be resolved without additional visits to the planet.

M. L. GOLDSTEIN
N. F. NESS
P. J. WASILEWSKI

GTP caused a concomitant increase in miscoding rate.

Another novel feature of this meeting was the devotion of a whole day to the question of ribosomal genetics. Large numbers of new mutant ribosomal proteins were described, which should prove useful in both genetic and functional studies, and some very impressive work on the ordering of individual genes within the *E. coli* chromosome was reported by S. Jaskunas and L. Lindahl (University of Wisconsin) Transducing phages carrying segments of bacterial DNA were isolated and the genes these contained could be identified using a DNA-dependent cell-free protein-synthesising system. The arrangement of the genes within the DNA segments was analysed with the help of restriction enzymes, and genes for rRNA, several factors, and many ribosomal proteins have at least been partially ordered in this manner.

Activity in these new areas meant that less time than usual was available for discussion of the more traditional aspects of ribosomal research. Little was heard in Brussels on the primary structures of ribosomal proteins and RNA, in order to avoid repetition of the extensive reports in this field which had been presented at the International Congress in Hamburg during the previous week. A number of delegates described protein–protein cross-linking, RNA–protein cross-linking and affinity labelling results, and here the picture of the *E coli* ribosome is becoming more and more complex. This is an obvious consequence of the irregularity of the protein shapes; as long as it was possible to think of the ribosome as a neat array of ping-pong balls, it was sufficient to identify which proteins were involved in a cross-link or affinity label experiment. Now that the ribosome has become a plate of spaghetti, researchers will be forced to push the analysis one stage further and identify the amino acid residues within the proteins which are involved in the reaction in order to be able to interpret the results fully, and this is not an easy task. For the same reason, the functional investigation of the *E. coli* ribosome has become more complex; more and more proteins are becoming implicated in each individual ribosomal function, and active participation of the rRNA is also now being frequently invoked, although here there is a notable lack of hard evidence. Nevertheless, various promising experimental approaches were reported, which should in due course converge on a clearer understanding of ribosomal function.

Finally, the eukaryotes had a short session to end the meeting. This session did not really do justice to the large amount of work now being done on the eukaryotic ribosome, which, roughly speaking, has reached the stage at which the *E. coli* work stood four years ago, in that (for example) ribosomal proteins are being isolated and characterised. Perhaps for this reason, the eukaryotic research seemed deceptively simple and straightforward at the moment, although the present state of the *E coli* ribosome can leave nobody with any illusions as to what lies ahead in the eukaryotic field. □

Familial dysautonomia

from Felicia Axelrod, Thomas W. Mittag and J. P. Green

The Familial Dysautonomia Foundation sponsored a conference on familial dysautonomia and related diseases at New York University Medical Center on May 14, 1976.

FAMILIAL dysautonomia is a rare autosomal recessive disorder characterised by specific dysfunctions in the autonomic nervous system and the sensory nervous system. Prominent manifestations include postural hypotension; excessive sweating; diminished perception of pain, temperature, hypoxia, and taste—the last associated with an absence of fungiform papillae in the tongue. The corneal reflex is absent and the deep tendon reflex diminished. After intradermal injection of histamine, the axon flare, one of Lewis's triple responses, does not occur. The patients can cry but there are no overflow tears because the lacrimal glands function poorly. Methacholine restores the tendon reflex and the histamine response and stimulates the lacrimal gland, but conscientious symptomatic and supportive therapy is the only means to prolong life.

An unusual characteristic of the disease is that some organs show supersensitivity to sympathomimetic and parasympathetic agents, as though denervated. A diminished number of unmyelinated nerve fibres as reported by A. A. Aguayo (McGill University) can account for some of these signs and symptoms. Similarly, J. Pearson (New York University) reported that dorsal root ganglia and sympathetic ganglia show a reduced number of normal neurones and the sympathetic ganglia contain a large number of cells resembling undeveloped neuroblasts. Additional evidence of peripheral nerve defects was presented by N. Grover-Johnson (New York University) who showed that blood vessels have a diminished number of autonomic nerve ending in these patients. By contrast the parasympathetic ganglia (ciliary and submaxillary) appear normal under the microscope (Pearson) even though it has long been known that in dysautonomic patients parasympathetically innervated structures such as the iris and lacrimal gland are supersensitive to parasympathomimetic drugs. E. Krikun and A. A Smith (New York Medical College) presented evidence that an isozyme of choline acetyltransferase was deficient in the basal ganglia of a patient dying of the disease, suggesting a basis for the parasympathetic defect. The apparent developmental arrest of unmyelinated axons and certain sympathetic neurones in familial dysautonomia led to investigations into a possible defect in nerve growth factor or other trophic factors. F. B. Axelrod (New York University) reported that nerve growth factor activity in the serum of these patients was within the normal range when measured by bioassay (the ability to stimulate growth of chick ganglion cell dendrites). Yet a recent report (Rogers *et al., Pediatric Res.,* **9,** 384; 1975 (Abstr. 764)) showed greater than normal concentration of the β-subunit of nerve growth factor in dysautonomic serum, measured by radioimmunoassay, but normal activity by bioassay. It was suggested (T. W. Mittag, Mount Sinai School of Medicine) that one possible explanation of this paradox is that patients have, in addition to the normal nerve growth factor, an abnormal nerve growth factor inactive in the chick bioassay but detectable by radioimmunoassay, which interferes with the action of normal nerve growth factor on human cells. There was general agreement that continuing studies of trophic factors that regulate the growth and development of autonomic and sensory nerves could be fruitful, perhaps leading to treatment and to prenatal diagnosis.

Although the disease is almost exclusively restricted to Ashkenazi Jews (in whom its frequency is 1 in 10,000) it was reported that some of the same signs and symptoms are present in other diseases such as idiopathic orthostatic hypotension (I. B. Black, Cornell University Medical College and A. Rubenstein, Mount Sinai School of Medicine) and diabetes mellitus (N. Grover-Johnson). The New York University group also reported that 75% of dysautonomics showed pathological changes in the renal glomeruli.

An understanding of the cause of familial dysautonomia will provide increased understanding of the development of the autonomic and sensory nervous systems. And, in turn, progress towards understanding the molecular basis of familial dysautonomia could come from investigations of other diseases manifesting autonomic dysfunction such as idiopathic orthostatic hypotension and diabetes mellitus.

A hundred years ago

IN connection with the general introduction of the now celebrated Liberian coffee plants into most of the coffee-producing countries, as noticed by Dr. Hooker in his recently issued report on Kew Gardens, we may draw attention to what our consul says on the decrease of the production of coffee in Cayenne The kind there cultivated is the Mocha, which at one time was an important staple of the colony, the country being especially adapted for its cultivation. This valuable product of Cayenne, although temporarily abandoned, is not lost to the world; the trees continue to thrive in a wild state, and may be reclaimed hereafter There are thousands of coffee trees interspersed in the forests of the inhabitable part of the colony which have been abandoned for years. They attain a height of about fifteen or sixteen feet, with a circumference, a few feet from the ground, of thirty inches; they are rich in foliage, but do not bloom. The coffee tree also appears to be safe from the ravages of insects, whereas many other trees suffer vitally from this evil.

THE proposal to submerge a portion of North Africa by means of a canal from the Gulf of Gabes, letting the water of the Mediterranean westwards over the lake region of Djerid, seems from the facts detailed by MM Roudaire and Dupuis to be not only a practicable, but also likely to turn out a remunerative undertaking. Owing to the comparatively small area it is proposed to submerge, the meteorological changes which the submersion would occasion can only be slight, strictly local, and altogether beneficial in their general tendency—differing absolutely in all these respects from the meteorological changes which would result from the submersion of the western portion of the Sahara, proposed some time ago. From this latter project it would follow, owing to the great extent of the water surface which would thus overspread the Western Sahara, and its proximity to the Atlantic, that the present disposition of the lines of atmospheric pressure would be seriously altered, a result necessarily attended with changes in the prevailing winds and and currents of the North Atlantic, seriously affecting international interests in a manner which our present knowledge does not enable us in any way accurately to predict.

The distribution of stars around a massive black hole

Stuart L. Shapiro & Alan P. Lightman
Centre for Radiophysics and Space Research, Cornell University, Ithaca, New York 14853

The stellar density distribution around a massive black hole at the centre of a spherical star cluster is determined from a simple scaling argument. The distribution is obtained by examining the net diffusion timescales associated with star and energy transport in a spherical, N*-body system in dynamic equilibrium. The same analysis is also used to determine the stellar density profile in the halo of a star cluster. The approximate distribution obtained here for a relaxed,* N*-body system with (or without) a central, massive black hole agrees qualitatively with the results of detailed numerical calculations.*

THE suggestion[1,2] that accretion on to a massive black hole ($M \sim 10^3 M_\odot$) might be responsible for the X-ray emission observed from globular clusters has stimulated new interest in the dynamical consequences of a collapsed object at the centre of an N-body system. Some confusion has arisen, however, concerning the resulting steady-state, stellar distribution near the black hole. In his pioneering analysis[3,4], Peebles used a simple scaling argument to suggest that the stellar density varied as

$$n(r) \sim n_a(r/r_a)^{-9/4}$$

in the region $r_t < r < r_a$. Here n_a is the central density of the isothermal cluster core,

$$r_a \sim GM/\langle v^2 \rangle$$

is the 'capture' radius within which core stars with velocity dispersion $\langle v^2 \rangle$ are bound to the black hole of mass M, and $r_t \ll r_a$ is the radius at which stars tidally disrupted by the black hole. All stars are assumed to have the same mass, m, with $m \ll M \ll M_c$, where M_c is the total cluster mass. Recently, more detailed calculations (J. Bahcall and R. Wolf, unpublished; A. P. L. and S. L. S., unpublished) have indicated that the appropriate density law near the black hole is more aptly described by the relation

$$n(r) \sim n_a(r/r_a)^{-7/4}$$

where the magnitude of the exponent decreases slowly with decreasing r because of the consumption of low angular momentum stars (A. P. L. and S. L. S., unpublished; J. Frank and M. J. Rees, unpublished).

Here we use a simple scaling argument to obtain the approximate density law $n(r) \propto r^{-7/4}$ and provide a simple explanation for the discrepancy between our derivation and the original argument suggested by Peebles. In particular, we emphasise the distinction and general inequality between the net energy diffusion timescale and the net particle diffusion timescale in an N-body system in dynamic equilibrium. We use the same analysis to determine the density distribution in the cluster halo surrounding the isothermal core. (The halo solution applies whether or not the cluster contains a black hole.) Thus, by careful delineation and the appropriate use of the two different timescales mentioned above, we obtain, in a few lines, the approximate stellar density distribution throughout a relaxed, spherical, N-body system containing a central black hole. As becomes evident, the analysis applies equally to any sufficiently massive compact object (for example, a supermassive star) at the centre of a star cluster.

Diffusion timescales in N-body systems in dynamic equilibrium

As a conservative, N-body system of identical point stars (mass m) approaches equilibrium stochastically through mutual gravitational encounters, stellar velocities change, and thus both energy and angular momentum are exchanged, on a relaxation timescale

$$t_R \sim \langle v^2 \rangle^{3/2}/(G^2 m^2 n).$$

If the entire stellar system were confined in a spherical container with perfectly reflecting walls, the system would achieve thermal equilibrium with no net flow of stars or energy out of the system. (Here we assume that the container radius is sufficiently small that the ratio of the central density to the density at the wall < 709. In this case the equilibrium is stable, and runaway evolution through the 'gravothermal instability' will not occur (see refs 5, 6).) If, however, the system is not confined by rigid walls and if, in addition, there exists a star 'sink' at its centre (for example, a black hole), significant departures from thermal equilibrium will exist near the centre and in the outer halo of the stellar system. The steady-state behaviour of the cluster in these distinct, non-thermal regions will be one of dynamic equilibrium, characterised by a constant net flux of stars and energy out of the two regions. As energy is continually exchanged between stars, a given group of stars occupying the radial zone between r and $2r$ in a non-thermal region will be scattered out of the zone in a time t_R. The timescale associated with the net diffusion of stars (or energy) across a sphere at r may, however, be considerably longer, since stars (and energy) from neighbouring radial zones are scattered into the zone between r and $2r$ in roughly the same timescale, t_R. Clearly, no physical quantity can be transported from one zone to the next on a net rate exceeding $\sim t_R^{-1}$. Only by examining the boundary layers of a given non-thermal region can one determine the net flux of stars and energy into the region. In general, the net energy and net particle diffusion timescales will not be equal and only the minimum of the two will equal t_R in any region in dynamic equilibrium.

Let the net star and net energy diffusion timescales at radius r in the cluster be denoted by $t_S(r)$ and $t_U(r)$, respectively. For a steady state, both the net star flux S and net energy flux U are constant and independent of radius. If $n(r)$ is the stellar density and $E(r)$ is the mean energy (per unit mass) at r, then the number of stars between r and $2r$ is $\sim nr^3$ and in the steady state we may write

$$S \sim \frac{n(r)r^3}{t_S(r)} = \text{constant} \qquad (1a)$$

$$U \sim \frac{n(r)r^3E(r)}{t_U(r)} = \text{constant} \qquad (1b)$$

In thermal equilibrium the constants on the right-hand sides of equation (1) are zero. In dynamic equilibrium, they are generally non-zero and equation (1) gives

$$t_U(r) \propto t_S(r)E(r) \qquad (2)$$

demonstrating the simple but important result that stars and energy do not, in general, diffuse on the same timescale in systems in dynamic equilibrium. The proportionality constant in equation (2) is obtained by analysis of the boundary conditions of the region of interest, as will be illustrated below. The resulting steady-state star distribution will always be valid whenever the local value of τ_R ($\sim 10^8$–10^9 yr in the cores of typical globular clusters) is much less than the timescale for the dynamic evolution of the cluster ($\sim 100\ \tau_R$ for evaporation (see below) and $\sim 10^{11}$ yr for a $10^3 M_\odot$ black hole to swallow its own mass of stars in a globular cluster (A.P.L. and S.L.S., unpublished; J. Frank and M. J. Rees, unpublished)).

Density distribution in a spherical cluster containing a central black hole

Equations (1a, b) and (2) may be used to determine the density distribution in a spherical cluster containing a massive black hole. The cluster may be conveniently divided into four distinct regions.

Region I: central cusp; $r_t < r < r_a$

This innermost region consists of negative energy stars bound to the central black hole. In steady state, the consumption of stars at r_t is balanced by a net inward flux of stars originating from the isothermal core at $r \gtrsim r_a$. Since bound stars of negative energy are removed at r_t, there exists a net outward flux of energy from this region, thereby allowing distant stars to move closer to the black hole to replenish the depleted star distribution. In this region $E(r) \sim -GM/r$, so from equation (2)

$$t_U \propto t_S r^{-1}$$

The absence of outgoing stars at r_t implies that the net diffusion time for stars to move from $2r_t$ to r_t equals the timescale for their (negative) energy to decrease by a factor of two. Thus $t_U(r_t) \sim t_S(r_t)$, and from equation (2)

$$t_U(r) \sim (r_t/r)t_S(r) \qquad (3)$$

For $r > r_t$, t_U is clearly the minimum timescale and can be equated to the relaxation timescale, $t_U \sim t_R \sim \langle v^2\rangle^{3/2}/(G^2m^2n)$. For bound stars near the black hole $\langle v^2\rangle \sim GM/r$, so equation (1b) yields

$$n(r) \propto r^{-7/4} \qquad (4)$$

The above result has been obtained previously (J. Bahcall and R. Wolf, unpublished; A. P. L. and S. L. S., unpublished) by detailed analysis of the steady-state diffusion of stars toward a central black hole. Peebles obtained equation (1a) and assumed the relation $t_S \sim t_R$, thereby overlooking the distinction between t_U and t_S and the fact that nearly equal ingoing and outgoing star fluxes at r result in a reduced net inward flux. His resulting solution

$$n(r) \propto r^{-9/4}$$

thus requires $t_U(r) < t_R(r)$, which forces stars at small radii $r' \ll r$ (and so small $t_R' \ll t_R$) to move towards r and results in a net outward star flux in violation of the boundary conditions. In region III of the globular cluster, t_S is the minimum diffusion timescale, rather than t_U, and there t_S can be equated to t_R legitimately.

Region II: isothermal core; $r_a < r < r_c$

In this region, which contains most of the cluster mass, thermal equilibrium prevails with a Maxwellian velocity distribution law and an isothermal density distribution law. To lowest order $S \sim U \sim 0$. In each relaxation time t_R (r_a), only those few high velocity stars on the tail of the distribution with velocities exceeding the escape velocity

$$\langle v_{esc}{}^2\rangle^{1/2} = 2\langle v^2\rangle^{1/2}$$

(roughly 1% of the total number) evaporate[7,8] from the core and populate the halo. The outer radius of the core r_c is determined by equating the local relaxation time $t_R(r_c)$ to the mean evaporation timescale, $\sim 100t_R(r_a)$; stars with $r > r_c$ cannot thermalise sufficiently rapidly to maintain thermal equilibrium in the presence of escaping stars. Since

$$t_R(r) \propto n^{-1}$$

in the isothermal core, we have

$$n(r_c)/n_a \sim 10^{-2}$$

or

$$r_c \sim 10/(12\pi G n_a m/\langle v^2\rangle)^{1/2}$$

where we use the standard isothermal profile in the region $r_a < r < r_c$. Detailed numerical calculations[9] confirm this qualitative picture.

Region III: halo; $r_c < r < r_{\varepsilon_2}$

The cluster halo is populated by high energy, bound stars ejected from the isothermal core. Halo stars move in highly eccentric orbits and, in each orbital period, penetrate the dense core where they suffer repeated, small angle gravitational encounters. Since all halo stars move with nearly the same velocity during their periastron passage through the core, they all experience roughly the same r.m.s. energy boost, ε_2, each period, independent of their energy E. Consequently, ε_2 is given by the (random walk) relation

$$\varepsilon_2 \sim \left(\frac{t_d}{t_R}\right)^{1/2} E = \text{constant} \qquad (5)$$

where

$$t_d \sim 2\pi G M_c/(2|E|)^{3/2}$$

is the ($\sim$ Keplerian) orbital period of a halo star of energy $E \sim -GM_c/r$. Equation (5) implies that

$$t_R(r) \propto r^{-1/2}.$$

In steady state, a constant net flux of stars moves outwards in the halo, providing a constant escape rate of positive energy stars ejected from the outermost halo or 'fringe' beyond $r \gtrsim r_{\varepsilon_2}$. At $r_{\varepsilon_2} \sim GM/\varepsilon_2$, stars can acquire positive energy in just one additional passage through the core. Since at r_{ε_2} there are no ingoing stars, we have, in analogy to the discussion for

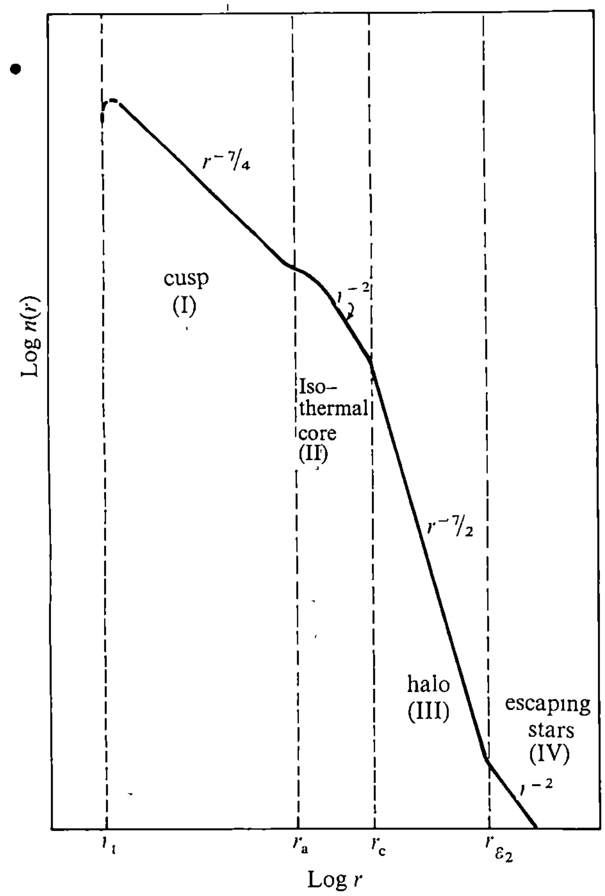

Fig. 1 The stellar density $n(r)$ as a function of radius r in a spherical cluster containing a massive, central black hole (see text for discussion of the different regions).

region I, $t_U(r_{\varepsilon_2}) \sim t_S(r_{\varepsilon_2})$. Equation (2) then implies

$$t_U(r) \sim (r_{\varepsilon_2}/r)t_S(r) \qquad (6)$$

In the halo, $r_c < r < r_{\varepsilon_2}$, t_S is now the minimum timescale; and so $t_S(r) \sim t_R(r)$. This disparity in diffusion timescales merely reflects the fact that energy is nearly conserved in a cluster experiencing stellar evaporation. Substituting

$$t_S(r) \sim t_R \sim r^{-1/2}$$

into equation (1a) yields the halo density distribution law

$$n(r) \propto r^{-7/2} \qquad (7)$$

Region IV: escaping stars; $r_{\varepsilon_2} < r < \infty$

In this non-thermal region, unbound, non-interacting stars with energy $E \sim \varepsilon_2$ move radially outwards to infinity with constant velocity

$$v_\infty \sim (\varepsilon_2)^{1/2}$$

A steady state requires $S \sim nv_\infty r^2 =$ constant, hence

$$n(r) \propto r^{-2} \qquad (8)$$

Similarly, $U \sim S\varepsilon_2 \sim$ constant. The above results derived for regions II–IV pertain with or without a central black hole, provided $M \ll M_c$. Detailed numerical calculations of the outer regions of a spherical cluster confirm[10] equations (7) and (8).

The entire run of the stellar density in a spherical cluster containing a central black hole is illustrated schematically in Fig. 1. For a $10^3 M_\odot$ black hole at the centre of the globular cluster NGC7078 (M15), where[11] $\langle v_\parallel^2\rangle^{1/2} \sim 10$ km s^{-1}, $n(r_a) \sim 5\times10^4$ pc^{-3} and $m \sim M_\odot$, the critical radii separating the different regions are (approximately) $r_t \sim 3\times10^{-7}$ pc, $r_a \sim 3\times10^{-2}$ pc, $r_c \sim 3$ pc, and $r_{\varepsilon_2} \sim 10^3$ pc. Since r_{ε_2} is larger than the tidal radius of the cluster in the galactic field, the stellar distribution in the outer halo will be modified as the energy required for escape falls below zero. By observing the stellar density distribution in the core of globular clusters with a large telescope, black holes with masses $> 10^3 M_\odot$ may be detected (J. Bahcall and R. Wolf, unpublished).

We thank E. E. Salpeter for several useful discussions, and the NSF for support.

Plutonium levels in Kwajalein Lagoon

V. E. Noshkin, R. J. Eagle & K. M. Wong

Biomedical and Environmental Research Division, Lawrence Livermore Laboratory, University of California, Livermore, California 94550

Reported plutonium levels in fish from both Kwajalein and Enewetak lagoons, suggest that Kwajalein Lagoon contains significantly more plutonium in its environment than would be expected from worldwide fallout levels alone, although quantities of plutonium greater than fallout concentrations have not been detected in the lagoon water. If there is no reason to reject the published fish data, then individuals on Kwajalein Atoll who supplement their diet with foods from the local marine environment may have plutonium body burdens similar to the low levels predicted for individuals on similar diets at Enewetak Atoll.

KWAJALEIN ATOLL (9°N 167°40′E) is located in the western (Ralik) chain of the Marshall Islands. In the same island chain and some 300 miles to the north-west is Enewetak Atoll (11°20′N 162°20′E), one of the United States nuclear testing sites during the 1940s and 1950s. It has been reported[1] that no immediate debris from the nuclear tests at Enewetak and Bikini (another Pacific test site) was deposited at Kwajalein. Measurements during 1972 and 1973 between 5 and 15°N, over a wide range of longitudes, indicated concentrations of between 0.22 and 0.44 pCi m^{-3} for ^{239,240}Pu in Pacific surface water[2,3]. The mean ^{239,240}Pu concentration in the surface waters of Kwajalein and other Pacific atoll lagoons located in this latitude band, therefore, would be expected to be similar to the surface oceanic level (0.34±0.11 pCi m^{-3}).

Table 1 Lognormal median concentrations of ^{239,240}Pu in fish tissues (pCi g^{-1} dry weight) collected at Enewetak and Kwajalein atolls*

*See refs 1 and 5.

†Values in parentheses are numbers of samples analysed. Average muscle and gut values in pCi g^{-1} dry weight can be converted to average pCi g^{-1} wet weight by dividing by 3.5.

This is not true of Enewetak Lagoon. In late 1972, the average measured concentration of ^{239,240}Pu in the lagoon surface water[3] was 39 pCi m^{-3}, approximately 100 times the level predicted from worldwide fallout. Clearly, some components of the atoll contaminated by fallout debris during the tests are contributing substantial amounts of ^{239,240}Pu to the lagoon water masses. The difference in ^{239,240}Pu concentrations between the two lagoons is a direct reflection of the activity levels in the environments of the two atolls. It also follows that if plutonium uptake in living organisms is expressed in terms of a concentration factor (the concentration of plutonium in the tissue of the marine organism divided by its concentration on an equivalent weight basis in the surrounding water), invertebrates, fish, or other marine organisms can be useful as indicator species of the level of environmental contamination.

Schell and Watters[4] have given ^{239,240}Pu concentrations in various organs of selected marine organisms collected at Enewetak and Kwajalein atolls. They concluded, however, that the plutonium and americium concentrations in the convict surgeon fish from Enewetak Atoll, for example, are not significantly higher than those measured at the control station, Kwajalein Atoll. The mantle and muscle tissues of a clam (*Tridacna* sp.) collected in the south-eastern region of Enewetak Atoll were, moreover, found to contain only one-sixth as much plutonium as those of a *Tridacna* sp. collected at Kwajalein Atoll[4]. On the other hand, the viscera and kidney of the same Enewetak Atoll clam had higher concentrations than those of the Kwajalein Atoll specimen.

In an assessment of the possible plutonium dose to man from food and other environmental pathways, Wilson *et al.*[5] compiled, in the form of lognormal median concentrations, all the plutonium survey data collected at Enewetak Atoll during 1972 and 1973 (ref. 1). The concentration values for all the fish muscle samples taken are reproduced here in Table 1, together with similar lognormal mean concentrations compiled from the same survey[1] data for fish bone and gut from Enewetak Atoll and muscle, bone, and gut concentrations, also from the same survey data[1], for fish collected off three islands of Kwajalein Atoll (W. R. Robison, private communication). Wilson *et al.*[5] found no significant differences in mean plutonium concentrations among four fish groups, which included, among others, planktonic and detritus feeders, grazing herbivores, bottom-feeding carnivores, and pelagic carnivores. Accordingly, they based their predictions of exposures to plutonium from ingestion of marine foods on the mean concentration of plutonium in the muscles of all the fish taken from the lagoon of Enewetak Atoll. Significantly, however, the ^{239,240}Pu in the lagoon water ranged from 1 to 96 pCi m^{-3} at the fish sampling sites[1].

Radionuclide concentration independent of environment?

The data of Schell and Watters[4], together with those of Table 1, show that average levels of ^{239,240}Pu in fish bone, muscle, and gut from Enewetak Atoll are similar to, or even lower than, those of the fish indigenous to the control station, Kwajalein Lagoon. There are several possible important conclusions that can be derived from these data. The first is that fish collected for consumption by man will contain, on average, essentially the same concentrations of plutonium radionuclides regardless of the source or level of plutonium in the local environment. Obviously, such a conclusion would greatly affect future plans for releasing low-level transuranics to the marine environment. Furthermore, it would force us to concede that the concept of a plutonium concentration factor for fish is meaningless. Also, it conflicts with a large body of plutonium concentration data for Atlantic fish species that derive their plutonium body burdens from worldwide fallout levels in the Atlantic Ocean. For example, for a number of Atlantic species, including bottom feeders, water-column feeders, and large predators[6-8], a lognormal median of all available bone concentration data is only 1×10^{-4} pCi g^{-1} (wet or dry), 900 times less than that for the bones of the Kwajalein fish (Table 1). A similar large discrepancy remains when the concentrations in the muscle of the Atlantic and Kwajalein fish are all normalised to an equivalent weight basis (wet or dry).

Plutonium levels in the Atlantic waters (where some of the fish were caught) range only between 0.2 and 1.1 pCi m^{-3}, according to Bowen *et al.*[8]. Calculating a concentration factor from the data for Atlantic fish and water and using a value of 0.4 pCi m^{-3} as the assumed mean plutonium level from fallout in the Kwajalein Lagoon, provides values of between 0.2 and 1.0 10^{-4} pCi g^{-1} for the bone of fish for this lagoon. These values are orders of magnitude lower than the lognormal median concentrations in Table 1. This discrepancy cannot be accounted for by any possible differences related to trophic levels or feeding habits. A similar calculation also yields large discrepancies between predicted and measured concentrations for fish muscle.

Excess plutonium at Kwajalein

An alternative explanation to account for these discrepancies would be that Kwajalein Lagoon contains significantly more plutonium in its environment than would be expected from worldwide fallout levels alone. To test this possibility, 55 l unfiltered water samples were collected during May and June of 1975 from the locations shown in Fig. 1. During June, two samples were also collected outside the Atoll in the north equatorial surface waters, to provide information on the plutonium levels in the open ocean in this region. Unfortunately, our schedule did not allow time to collect fish on Kwajalein Atoll.

The water samples were analysed for ^{239,240}Pu and ^{137}Cs using the methods described in refs 9 and 10. Our analytical results are shown in Table 2. Although the lagoon was not sampled in great detail, the data are sufficient to show that the average ^{239,240}Pu concentration in Kwajalein Lagoon (0.45 ± 0.21 pCi m^{-3}) is nearly the same as the mean for the surface water of the ocean in the area, and that it agrees reasonably well with the levels previously predicted from worldwide fallout.

At the time the Kwajalein water samples were being processed we were also participating in an intercomparison exercise with Woods Hole Oceanographic Institution to determine ^{239,240}Pu levels in replicate surface-water samples from one location in the North Atlantic. The mean value for eight samples from Woods Hole (V. T. Bowen, unpublished) was 0.63 ± 0.16 pCi m^{-3}, whereas ours for 10 samples was 0.70 ± 0.30 pCi m^{-3}. This analytical agreement (as well as that in other national and international intercomparisons that we have completed) lends a measure of confidence to our data. In addition, these comparative data show that, as expected from worldwide depositional data[11], average plutonium levels are somewhat lower in Kwajalein Lagoon than in North Atlantic surface waters. The average ^{239,240}Pu/^{137}Cs ratio of 0.0032 for Kwajalein Lagoon is also in good agreement to the average value for open ocean, in contrast to the ratio of 0.07–0.12 in the Bikini and Enewetak lagoons[3]. This illustrates that both the ^{239,240}Pu and the ^{137}Cs content of the lagoon are derived from worldwide fallout.

We are still without an obvious explanation for the discrepancy in the fish-tissue data; that is, why should the Kwajalein fish, in a region of the equatorial Pacific contaminated only by worldwide fallout, have significantly higher body burdens of plutonium than fish in the North Atlantic which is also contaminated only with worldwide fallout? Furthermore, why do the Kwajalein Atoll fish have the same or even higher body burdens than the fish at Enewetak Atoll, where higher levels of plutonium are found in the lagoon? And why were the concentrations in Enewetak Lagoon fish not correlated with those in the specific local environment where they were sampled, or with feeding habit or trophic level? A cursory search of the literature surprisingly revealed only one other relevant fallout report—the plutonium level in the body of a single marine fish in fallout-contaminated waters of the Pacific[12]. The plutonium concentration in this sample and the computed concentration factor are closer to those from the North Atlantic fish than to those from Kwajalein. On the other hand, plutonium levels in tissues from catfish from Trombay[13], in plaice from the vicinity of Windscale[14], and in several species from areas of Thule[15] are higher than those in the tissues of the North Atlantic fish, and close in value to those from Kwajalein and Enewetak. But as the last three sets of data are from areas known to have local plutonium contamination from reprocessing plants (and one nuclear accident), they support our argument that levels of plutonium in fish reflect local environmental levels.

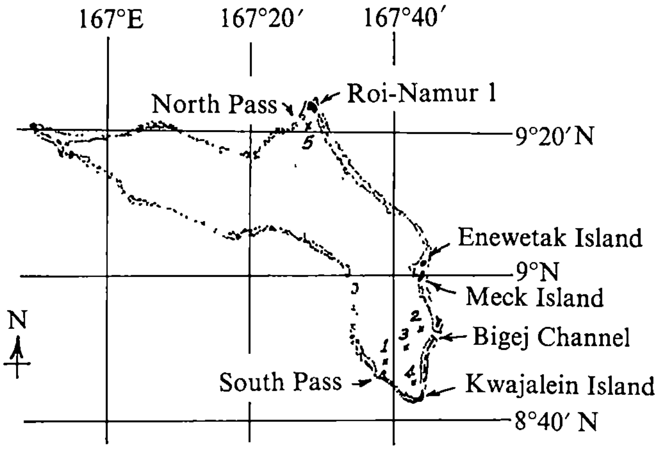

Fig. 1 Locations of sampling sites (see Table 2).

To sum up, it appears that available plutonium data from fish tissues are inconsistent. If we accept the available Enewetak and Kwajalein Atoll data as correct, then we can only conclude that the availability to all fish and invertebrates of plutonium from fallout, or for that matter from any local source, depends more on the type of environment than on the plutonium levels in that environment. The data could also suggest that coral atolls may have specific biogeochemical processes that regulate the availability of plutonium regardless of levels in the environment or in food. On the other hand, if we assume that concentrations in fish and invertebrates are proportional to those in the environment, then we can only conclude that many of the atoll fish data from the laboratories involved in analytical programmes[1,4] are in error. Since there is no other evidence at this time to refute the analytical results from the atolls, we can only urge caution in applying concentration factors measured in one marine area to predict approximate plutonium levels in fish from other marine areas. In addition, it seems, on the basis of the published data[1,4] and the summary assembled in Table 1, that individuals on Kwajalein Atoll who supplement their diet with foods from the local marine environment may have plutonium body burdens similar to the low levels predicted[5] for individuals at Enewetak on similar diets.

Table 2 Concentrations of ^{239,240}Pu and ^{137}Cs (pCi m^{-3}) in seawater in Kwajalein Lagoon and two locations in north equatorial waters

Identification of phage SP01 proteins coded by regulatory genes *33* and *34*

Thomas D. Fox*

Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138

Bacillus subtilis *phage SP01 induces polypeptides of 24,000 and 13,500 daltons that are bound to a form of RNA polymerase that directs phage "late" transcription* in vitro. *These proteins are the products of SP01 genes* 34 *and* 33, *regulatory cistrons that control "late" gene expression* in vivo.

GENE expression during the lytic cycle of *Bacillus subtilis* phage SP01 is controlled in a temporally defined sequence[1]. Phage "early" genes are transcribed almost immediately after infection and this RNA synthesis is directed by the sigma subunit of the host RNA polymerase. Next, phage "middle" genes are turned on at 4–5 min into the lytic cycle; this transcription is activated by the protein product of SP01 regulatory gene *28* (refs 2 and 3). Gene *28* is now known to code for a phage-induced protein that binds to *B. subtilis* RNA polymerase[4] and that apparently directs specific transcription *in vitro* in the absence of sigma factor[5–8]. A host protein, δ, has been described that improves the accuracy of middle-gene transcription by the phage-modified RNA polymerase.

Activation of SP01 "late" genes between 8 and 14 min into the lytic cycle seems to require a further modification of RNA polymerase. Pero *et al.*[6] have shown that a form of the *B. subtilis* transcriptase containing phage-induced subunits of 24,000 (termed V) and 13,500 (termed VI) daltons preferentially copies 'late' genes *in vitro*. The work reported here establishes that these phage-induced subunits are coded by SP01 genes *34* and *33*, regulatory cistrons that control late gene expression *in vivo*[2,3]. An accompanying article[9] demonstrates that the purified protein products of genes *33* and *34* and host delta factor act synergistically to direct the synthesis of late RNA by core RNA polymerase.

Induction of polypeptides V and VI by mutants

As an initial step in investigating the possible relationship of phage-induced polypeptides VI and V, to genes *33* and *34*, the synthesis of these proteins in bacteria infected with wild-type SP01 was examined. Cells of a non-suppressing (su^-) strain of *B. substilis* were infected with wild-type phage and pulse labelled with ^{35}S-methionine at an intermediate time in the lytic cycle. RNA polymerase was isolated from an extract of the infected cells by gel filtration and phosphocellulose chromatography. The enzyme was radiochemically highly purified at this stage of purification and contained essentially only host subunits of RNA polymerase and previously identified phage-induced proteins that copurify with polymerase[10]. Phosphocellulose-purified polymerase was then analysed by the two-dimensional gel electrophoresis procedure of O'Farrell[11]; radioactive enzyme was denatured in urea and subjected to isoelectric focusing in the first dimension and sodium dodecyl sulphate (SDS) slab gel electrophoresis in the second dimension. Figure 1*a* is an autoradiogram of a region of the two-dimensional gel that contained a 26,000-dalton polypeptide termed IV (the product of gene *28*)[4], polypeptide V (24,000) and polypeptide VI (13,500). The approximate isoelectric points of proteins IV, V and VI were 5.4, 7.3 and 7.4 respectively. The identification of these proteins was confirmed by a mixing experiment in which the radioactive phosphocellulose-purified polymerase was coelectrophoresed in two dimensions with unlabelled phage-modified enzymes from a previous study[5].

High resolution two-dimensional gel analysis also made possible the identification of polypeptides V and VI in crude extracts of SP01-infected bacteria. Radioactive protein extracted from bacteria infected with wild-type phage was subjected to two-dimensional electrophoresis. Figure 1*b* is an autoradiogram of a region of the gel corresponding to that of Fig. 1*a* and containing polypeptides IV, V, and VI. Since the relative position of spots varied somewhat from gel to gel, it was necessary to identify the phage-induced subunits of RNA polymerase by means of a mixing experiment (not shown) in which radioactive enzyme of Fig. 1*a* was coelectrophoresed with the crude extract of Fig. 1*b* (and with extracts of mutant-infected bacteria described below) Polypeptides V and VI were well resolved from other radioactive proteins and are designated with arrows. Polypeptide IV on the other hand, was partially occluded by another intensely labelled protein and is not designated in the figure.

To examine the effect of a mutation in gene *34* on the synthesis of the phage-induced subunits of polymerase, the su^- bacteria were infected with the nonsense mutant *sus*F4 (refs 2 and 3) and radioactively labelled at an intermediate time in the lytic cycle. Two-dimensional analysis revealed that polypeptide V was specifically lacking in both phosphocellulose-purified polymerase (Fig. 1*c*) and unfractionated extract (Fig. 1*d*) from the mutant-infected cells. This finding is consistent with the possibility that subunit

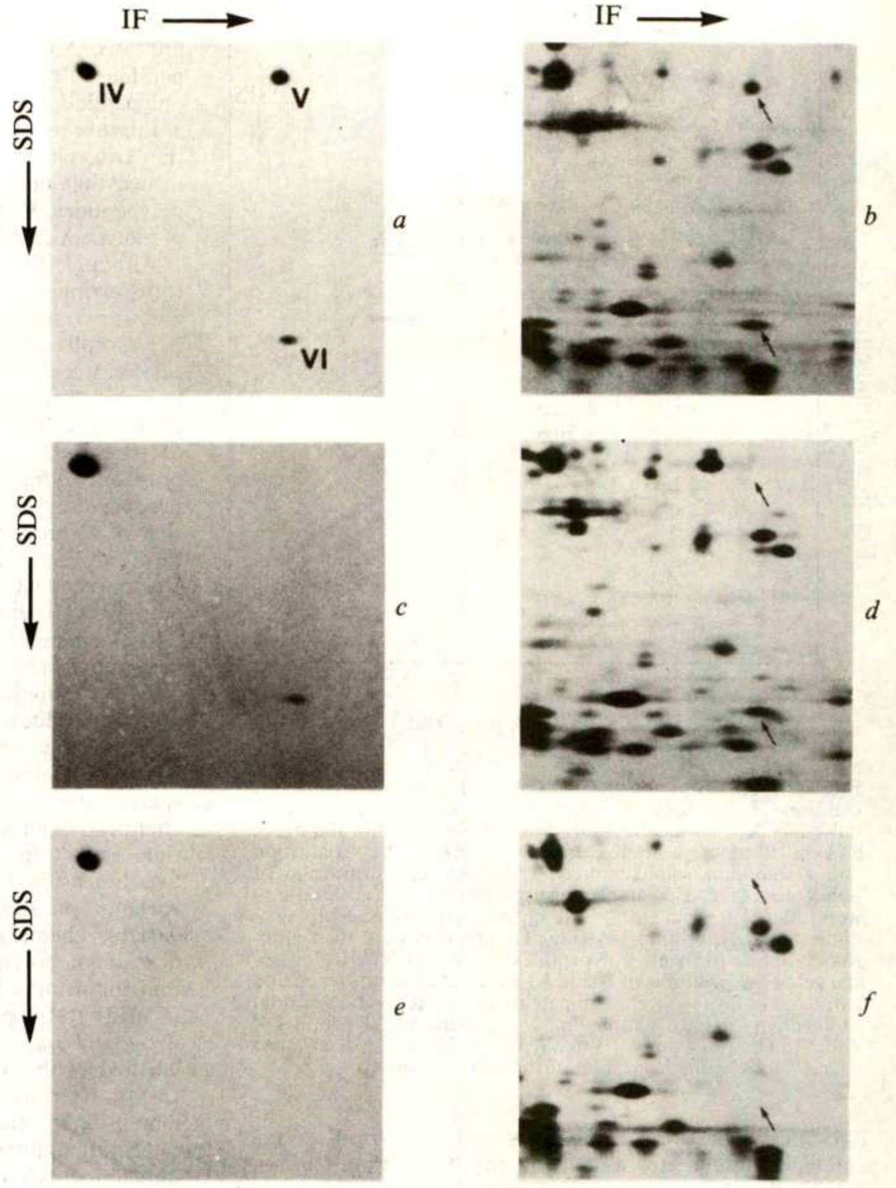

Fig. 1 Two-dimensional electrophoresis of subunits IV, V and VI in RNA polymerase and in crude extracts from non-suppressing bacteria infected with wild-type and mutant phage. The *su*⁻ strain was a methionine prototrophic derivative of *B. subtilis* Mu8u5u6 (ade⁻, leu⁻, met⁻)[12] and was obtained from A. L. Sonenshein. Cells were grown at 37 °C in a modification of 121A medium[13] containing leucine (50 μg ml^{-1}) and adenine (100 μg ml^{-1}). Cultures of the bacteria (150 ml) were labelled by the addition of 2 mCi of ^{35}S-methinoine (high specific activity; prepared as described before[14]) 10–14 min after infection with the mutant (obtained from S. Okubo) and wild-type phage indicated below (multiplicity of infection 5). RNA polymerase (*a*, *c* and *e*) was purified from 0.3 g of infected cells as described before[4], concentrated by trichloroacetic acid precipitation[10] and dissolved in "lysis buffer" (ref. 11, modified to contain 2% ampholines (LKB) *p*H range 3–10). Crude extracts (*b*, *d* and *f*) were prepared from 6 mg of infected cells as follows. Infected cells were suspended in 0.2 ml of buffer containing 0.01 M Tris-HCl (*p*H 7.9), 0.01 M EDTA and lysozyme (300 μg ml^{-1}), incubated for 1 h at 0 °C and then disrupted by brief sonication. Next, $MgCl_2$ (to 0.02 M), RNase and DNase (to 50 μg ml^{-1}) were added. After low speed centrifugation, the resulting supernatant fluids were incubated at 0 °C for 1 h and then added at room temperature to 0.43 ml of the modified "lysis buffer" containing an additional 235 mg of urea. Samples of RNA polymerase (~10^5 c.p.m.) and of crude extract (~2.3×10^6 c.p.m.) in the "lysis buffer" were then subjected to isoelectric focusing as described by O'Farrell[11] but with the following modifications. The gels contained 5.4% polyacrylamide[4] and 1.9% ampholines (LKB) comprised of 1.5% *p*H range 3–10, 0.2% *p*H range 9–11, 0.1% *p*H range 5–7 and 0.1% *p*H range 4–6. The lower electrode (cathode) solution contained 0.4% ethylenediamine. The isoelectric focusing gels were then subjected to electrophoresis in a second dimension through discontinuous SDS slab gels as described[4]. (It should be noted that the separation of subunits IV and V in discontinuous SDS gels is strongly dependent on the commercial brand of SDS (J. Pero, J. Nelson and T.D.F., unpublished results and ref. 15) and that the separation achieved here using a crystalline form of SDS from BioRad is less than was previously obtained using SDS in powdered form from BioRad (refs 5 and 6) and less than can be obtained using SDS from Pierce Chemical Co. (unpublished results).) Each picture is an autoradiogram[16] (100 h exposure) of a region of the two-dimensional gels to which subunits IV, V and VI migrate. The following samples were subjected to electrophoresis: *a*, RNA polymerase from bacteria infected with wild-type SP01; *b*, crude extract of bacteria infected with wild-type SP01; *c*, RNA polymerase from bacteria infected with the mutant *sus*F4; *d*, crude extract of bacteria infected with the mutant *sus*F4; *e*, RNA polymerase from bacteria infected with the mutant *sus*F14; *f*, crude extract of bacteria infected with the mutant *sus*F14. The IF (isoelectric focusing) arrows point in the direction of increasing *p*H; the SDS arrows point in the direction of decreasing molecular weight. The arrows in the autoradiograms of crude extracts indicate the positions of subunits V and VI.

V is the product of gene *34*.

Figure 1*e* and *f* shows the effect of a nonsense mutation in gene *33*, *sus*F14 (refs 2 and 3), on the induction of the phage-induced subunits. Surprisingly, *su*⁻ bacteria infected with the gene *33*⁻ mutant failed to synthesise detectable quantities of both polypeptides VI and V (although in experiments comparable with Fig. 1*f* faint traces of a protein in the position of V were observed). This finding is consistent with an assignment of subunit VI as the product of gene *33* if, as discussed below, the *sus*F14 mutation in gene *33* somehow interferes with the synthesis of polypeptide V, the putative product of gene *34*.

Although mutations in either gene *33* or gene *34* alone interfere with the global transcription of late genes[2,3], close inspection of Fig. 1 reveals certain protein species whose synthesis is blocked uniquely in either the gene *33*⁻ or the gene *34*⁻ mutants. While this has yet to be investigated, the kinds of arguments used to explain the pleiotropic effect of *sus*F14 on the synthesis of polypeptide V (see below) could be applied here.

The ability to detect polypeptides V and VI in crude extracts by means of two-dimensional gel analysis made it possible to determine whether the synthesis of these proteins is induced at a middle time in the phage lytic cycle, as would be expected for regulatory proteins that control late gene expression. Bacteria were infected with wild-type SP01 and then pulse labelled at various times after infection. Crude extracts of the infected cells were then subjected to two-dimensional gel electrophoresis. Figure 2 indicates the proportion of total radioactivity that was incorporated into proteins V and VI during each pulse-labelling period. These results indicate that the synthesis of polypeptides V and VI was turned on synchronously at a middle time in the lytic cycle, after the appearance of polypeptide IV, the product of the early gene *28*, but before the onset of late protein synthesis (not shown).

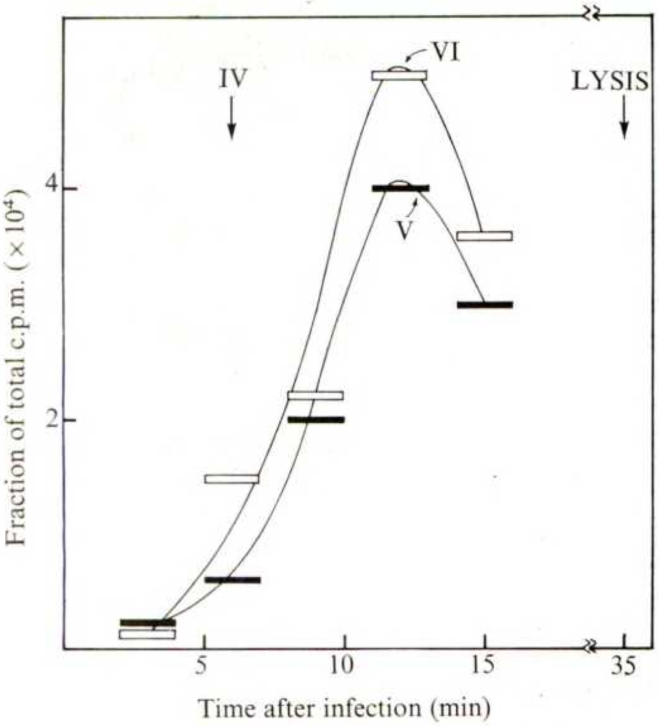

Fig. 2 Time course for the induction of subunits V and VI. Cultures of *su*$^-$ bacteria were infected with wild-type SP01, pulse labelled during the 2-min intervals indicated in the figure and chilled quickly. Crude extracts were prepared by sonication and ammonium sulphate precipitation as for purification of polymerase (Fig. 1). Samples of each extract ($\sim 8 \times 10^6$ c.p.m.) were diluted tenfold into "lysis buffer" and subjected to two-dimensional electrophoresis (Fig. 1). The gels were then autoradiographed to locate polypeptides IV, V and VI. Regions of the gel in the positions of V and VI were cut out, moistened and extracted in Protosol. The ordinate indicates the fraction of total radioactivity in each sample that was present in polypeptides V and VI. The peak time of subunit IV synthesis was determined by visual inspection of the autoradiograms.

(Two-dimensional electrophoresis did not resolve polypeptide IV sufficiently well to quantitate its time course of appearance. But the synthesis of this regulatory protein could be followed by visual inspection of the autoradiograms, and the arrow in Fig. 2 indicates the peak time of subunit IV synthesis.) The findings of Fig. 2 agree with a study[10] that compared the time of appearance of polypeptides IV and V in association with RNA polymerase at different times in the lytic cycle.

Gene *34* codes for subunit V

To test directly whether subunit V is the protein product of gene *34*, the gene *34*$^-$ nonsense mutant *sus*F4 was grown in two different suppressor (*su*$^+$) strains of *B. subtilis* that carried the nonsense suppressors *sup-1*[17,18] and *sup-3*[19,20] in isogenic backgrounds. The *sup-1* and *sup-3* suppressors are thought to insert different amino acids[12] and a recent study in this laboratory[4] indicated that the amino acid inserted by *sup-3* is more basic (or less acidic) than the residue inserted by *sup-1*. Thus, if subunit V is the product of gene *34*, then polypeptide V generated by suppression of *sus*F4 with *sup-3* ought to be slightly more basic than the corresponding protein generated by suppression with *sup-1*. This strategy was previously used to assign subunit IV as the product of gene *28* (ref. 4).

To test the prediction that suppression would generate altered forms of polypeptide V, radioactively labelled RNA polymerase was separately purified by phosphocellulose chromatography from *sus*F4-infected bacteria carrying either *sup-1* or *sup-3*. The phosphocellulose-purified enzymes were then subjected to two-dimensional gel electrophoresis. A comparison of Fig. 3*a* and *b* suggests that polypeptide V from *sup-3* bacteria was slightly more basic than polypeptide V from the *sup-1* bacteria. Electrophoresis of a mixture of the phosphocellulose-purified enzymes from the two phage-infected suppressor-strains (Fig. 3*c*) confirmed that nonsense suppression had generated variants of polypeptides V but had not affected the isoelectric points of polypeptides IV and VI.

Although the two supressor strains were constructed by transferring (by means of genetic transformation) the *sup-1* and *sup-3* suppressors into the same genetic background, it was still conceivable that the altered forms of polypeptide V were caused by some unknown difference between the suppressor strains other than the nonsense suppressors themselves. Therefore, to examine whether the generation of variants of polypeptide V was related directly to suppression of the *sus*F4 mutation, the isoelectric point of V produced by *sus*F4 in *sup-3* bacteria was compared with that of V produced by a spontaneous revertant of *sus*F4 in the same *sup-3* strain. Figure 3*d* and *e* shows that subunit V induced by the revertant was less basic than the corresponding polypeptide induced by the nonsense mutant. (Subunit V induced by the revertant in *sup-3* bacteria was indistinguishable from the corresponding protein generated by suppression of *sus*F4 in *sup-1* bacteria or the protein produced by wild-type SP01 in *su*$^-$ bacteria.)

A possible complication in analysis of the isoelectric points of proteins is that charge changes in a single protein species can arise artefactually *in vitro* as a result of chemical modification, and cause the appearance of "multiple spots" in the isoelectric focusing dimension of the two-dimensional gels[11]. To eliminate the possibility that the variants of subunit V had actually been produced by variable chemical modification *in vitro*, either during purification of polymerase or during two-dimensional analysis, the following 'double-label' mixing experiment was performed. RNA polymerase was purified from a mixture of *sup-1* and *sup-3*-carrying bacteria that had been separately labelled with ^{3}H-methionine and ^{35}S-methionine, respectively, after infection with the mutant *sus*F4. After two-dimensional electrophoresis, the distribution of each radioisotope in the isoelectric focusing dimension was determined for subunits IV, V and VI. While the distribution of both radioisotopes was identical for polypeptides IV and VI (Fig. 4*a* and *c*), the ^{35}S radioactivity in subunit V from the *sup-3* bacteria was in a more basic position than the ^{3}H radioactivity from the *sup-1* strain (Fig. 4*b*). The reverse "double-label" mixing experiment (not shown), with ^{35}S-labelled *sup-1* bacteria and ^{3}H-labelled *sup-3* bacteria, confirmed that the form of subunit V induced by *sus*F4 in *sup-3* cells was more basic than that induced by the mutant in the *sup-1* strain.

Gene *33* codes for subunit VI

If subunit VI is the product of gene *33*, then suppression of the gene *33*$^-$ nonsense mutation, *sus*F14, should generate altered forms of polypeptide VI without affecting the isoelectric point of subunits IV and V. The experiment shown in Fig. 3 confirms this prediction; *sus*F14 growing in *sup-3* bacteria produced a more basic form of VI (Fig. 3*g*) than that produced by *sus*F14 in *sup-1* bacteria (Fig. 3*f* and *h*) or that produced by a spontaneous revertant of *sus*F14 in *sup-3* bacteria (Fig. 3*i* and *j*) (or that produced by wild-type phage in *su*$^-$ bacteria).

Close examination of Fig. 3*i* and *j* reveals a faint spot of radioactivity on the acidic side of VI; this is probably attributable to charge heterogeneity introduced *in vitro* as referred to above. The "double-label" mixing experiment of Fig. 4 (as well as a corresponding experiment with the radioactive isotopes reversed) eliminates the possibility,

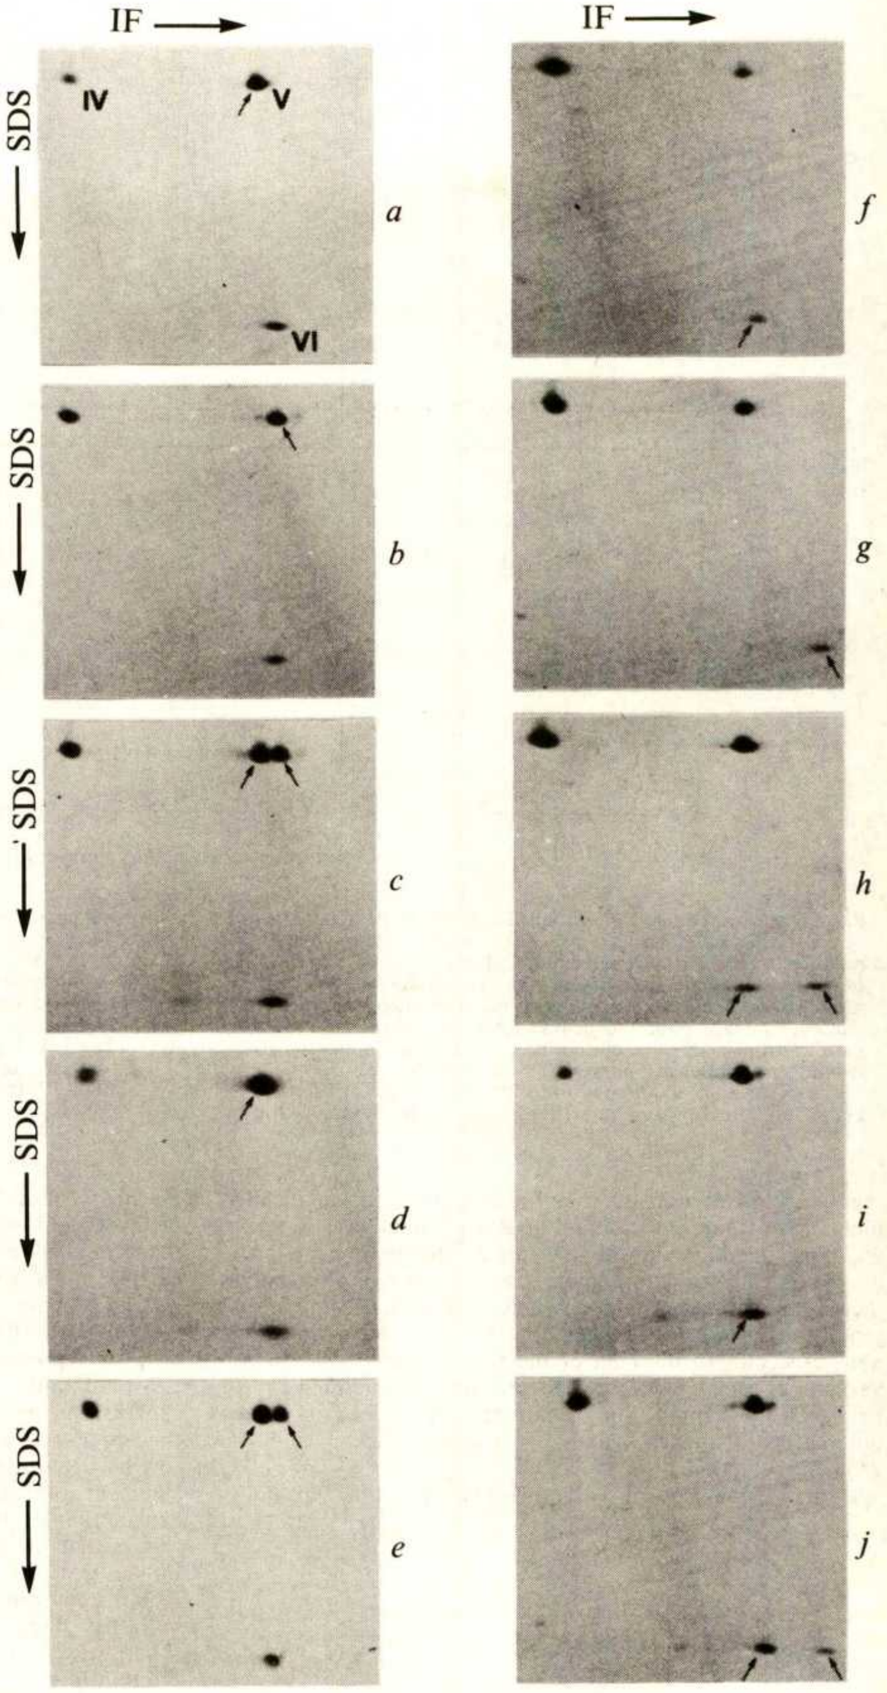

Fig. 3 Two-dimensional electrophoresis of RNA polymerase from *sup-1* and *sup-3* bacteria infected with SP01 nonsense mutants. Strains of *B. subtilis* carrying the nonsense suppressors *sup-1* and *sup-3* in isogenic backgrounds were constructed by transformation[21] of the su^- strain Mu8u5u6 (Fig. 1) with DNA from the *sup-1* strain HA-101-B (ref. 15) and the *sup-3* strain su^+3 (ref. 17). Suppressor-carrying transformants were isolated by selecting simultaneously for adenine and methionine prototrophy; the *purB6* and *metB5* mutations in Mu8u5u6 are suppressable markers[12,19]. Purification and two-dimensional electrophoresis of RNA polymerase from phage-infected cells were as described in the legend to Fig. 1 except that the bacterial growth medium did not contain adenine. The autoradiograms are from electrophoreses of the following enzymes: *a*, RNA polymerase from *sup-1* bacteria infected with the mutant *sus*F4 (gene *34*$^-$); *b*, RNA polymerase from *sup-3* bacteria infected with the mutant *sus*F4 (gene *34*$^-$); *c*, a mixture of the enzymes from the experiments of *a* and *b*; *d*, RNA polymerase from *sup-3* bacteria infected with a spontaneous revertant of the mutant *sus*F4 (isolated by plating mutant phage on su^- bacteria); *e*, a mixture of the enzymes from the experiment of *b* and *d*; *f*, RNA polymerase from *sup-1* bacteria infected with the mutant *sus*F14 (gene *33*$^-$); *g*, RNA polymerase from *sup-3* bacteria infected with the mutant *sus*F14 (gene *33*$^-$); *h*, a mixture of the enzymes from the experiments of *f* and *g*; *i*, RNA polymerase from *sup-3* bacteria infected with a spontaneous revertant of the mutant *sus*F14 (isolated by plating mutant phage on su^- bacteria); *j*, a mixture of the enzymes from the experiments of *g* and *i*.

however, that the difference in charge of the *sup-1* and *sup-3*-generated variants of polypeptide VI could have been caused completely by variable chemical modification introduced *in vitro*. Figure 4 also confirms that suppression of the gene *33*$^-$ nonsense mutant had specifically affected the isoelectric point of VI (Fig. 4*f*) without affecting subunits IV (Fig. 4*d*) or V (Fig. 4*e*).

Scheme for regulation

The finding that altered forms of polypeptides V and VI can be generated independently by suppression of nonsense mutations in SP01 genes *34* and *33* strongly suggests that these phage-induced subunits of RNA polymerase are coded by the regulatory cistrons that control late gene expression. A complicated alternative interpretation is that the SP01

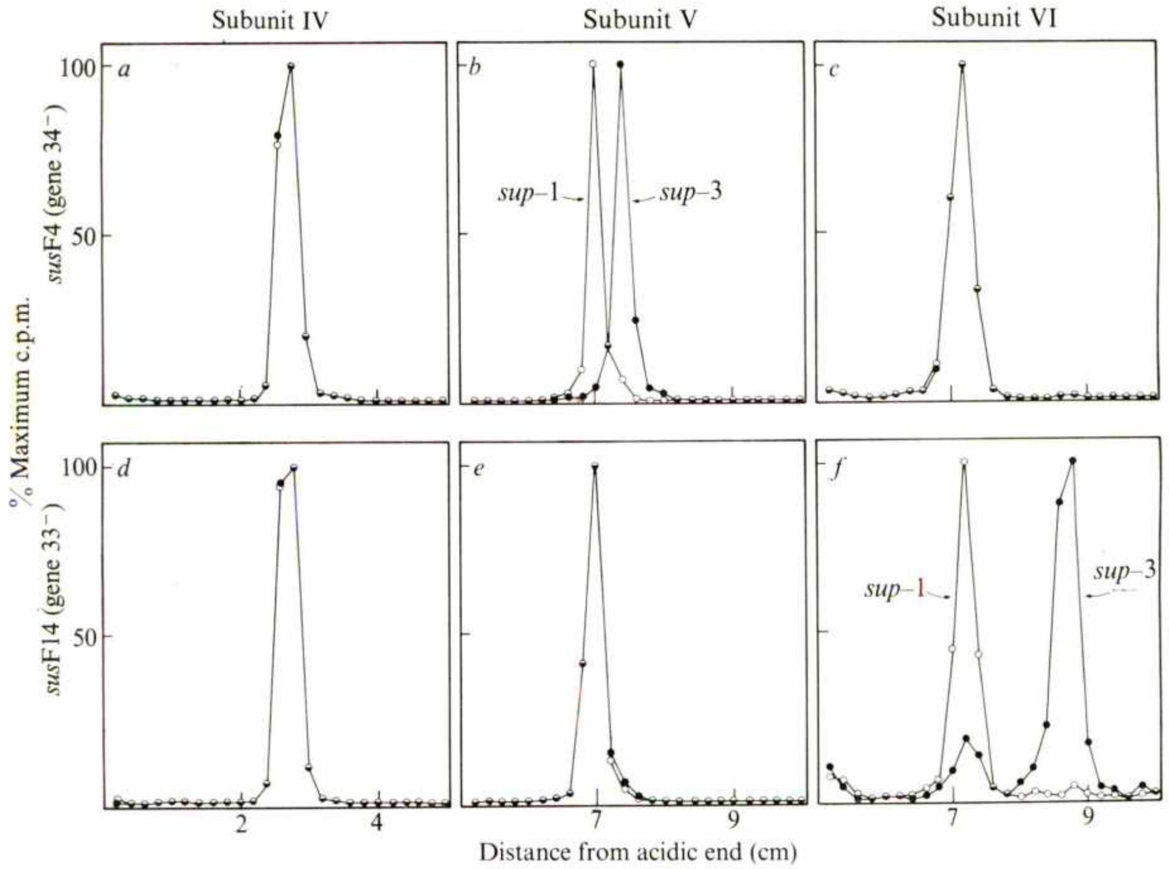

Fig. 4 Isoelectric focusing of subunits IV, V and VI from mixtures of *sup-1* and *sup-3* bacteria separately labelled with different radioisotopes after phage-infection. Cultures of *sup-1* and *sup-3* bacteria were labelled separately with ^{3}H-methionine (Schwarz/ Mann) and ^{35}S-methionine respectively, after infection with the nonsense mutant indicated below. RNA polymerase was then purified from a mixture of the infected cells and subjected to two-dimensional electrophoresis as described in the legend to Fig. 1. After autoradiography to locate the position of subunits IV, V and VI, strips were cut from the gels along the isoelectric focusing dimension at the positions of IV, V and VI in the SDS dimension. Each strip was then cut into 2-mm slices and the amount of ^{3}H (○) and ^{35}S (●) in each slice was measured in a scintillation counter after moistening and extracting the slices in Protosol. *a–f* show the distribution of each radioisotope along the IF dimension in *a*, subunit IV from *sus*F4 infected cells; *b*, subunit V from *sus*F4-infected cells; *c*, subunit VI from *sus*F4-infected cells; *d*, subunit IV from *sus*F14-infected cells; *e*, subunit V from *sus*F14-infected cells; *f*, subunit VI from *sus*F14-infected cells.

regulatory genes actually code for enzymes that chemically modify SP01-induced subunits of RNA polymerase *in vivo*, and that modifications by the *sup-3*-suppressed gene products somehow generate more basic (or less acidic) polymerase subunits than modifications by the *sup-1* suppressed gene products. This interpretation, however, seems improbable, especially in the light of the fact that isoelectric point variants of three different proteins can be generated independently by suppression of nonsense mutations in three different SP01 genes (genes *33* and *34*, Figs 3 and 4; gene *28*, ref. 4).

If these gene-product assignments are correct, why does the *sus*F14 mutation in gene *33* prevent the normal synthesis of the gene *34* protein (Fig. 1)? Since genes *33* and *34* are tightly linked on the genetic map of SP01 (ref. 3), one possible explanation is that the regulatory cistrons that control late transcription are located in the same operon and that the *sus*F14 nonsense mutation exerts a "polar" effect on the expression of gene *34*. But since the *sus*F4 and *sus*F14 mutants complement each other (albeit weakly)[3], this explanation demands that the *sus*F14 mutant actually synthesises a small amount of the gene *34* protein (smaller than can be detected in Fig. 1) and that this small quantity is sufficient to promote late gene expression. Another possible explanation of the pleiotropic effect of the *sus*F14 mutation is that the expression of gene *34* is controlled directly by the gene *33* protein. This possibility is not necessarily inconsistent with the time course experiment of Fig. 2, or with the finding that the genes *33* and *34* proteins act synergistically to alter the global pattern of SP01 transcription *in vitro*[9].

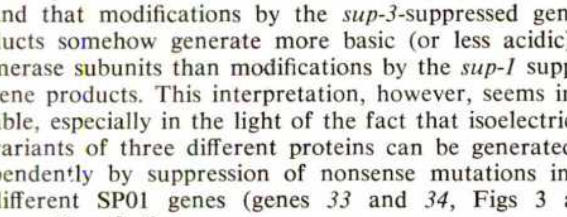

Fig. 5 Proposed model for the temporal control of phage SP01 gene expression. The figure illustrates schematically the three major categories of SP01 gene transcription; the figure is not intended to represent the actual physical arrangement of early, middle and late genes on the phage genome or the number and arrangement of promoter sites. The cross-hatched ellipses represent the host subunits of RNA polymerase other than sigma factor.

In conjunction with the previous finding that regulatory gene *28* codes for a phage-induced subunit of RNA polymerase[4], the further gene-product assignments reported here suggest the following scheme for the temporal control of phage SP01 gene expression (Fig. 5). Immediately on infection, host sigma factor directs the transcription of phage early genes. Next, at an intermediate time in the lytic cycle the gene *28* protein (itself the product of an early gene) turns on the expression of middle genes by binding to the host polymerase in the place of sigma factor. Finally, the gene *33* and *34* proteins (the products of middle genes) bind to the host transcriptase and activate late gene expression. This scheme is undoubtedly an oversimplification since it does not account for the turn off of subclasses of the early and middle genes at different times in the lytic cycle (see ref. 1). In analogy with the model of Fig. 5, the coliphage T4 regulatory genes that control late gene expression code for proteins that bind to the host RNA polymerase[22-24].

I thank J. Pero and R. Losick for helpful discussions, A. L. Sonenshein for assistance with genetic transformations and R. Losick for help with the manuscript. This work was supported by a grant from the NSF.

Bacteriophage SP01 regulatory proteins directing late gene transcription *in vitro*

Robert Tjian & Janice Pero

Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138

Expression of the temporally defined "late" genes of Bacillus subtilis *phage SP01 requires the protein products of regulatory genes* 33 *and* 34. *These proteins have now been isolated in pure form. Together with a host factor delta, they act synergistically to direct "late" gene transcription* in vitro *by core RNA polymerase.*

THE temporal programme of gene expression by *Bacillus subtilis* phage SP01 is controlled by phage-coded regulatory proteins that interact with the bacterial RNA polymerase (for a review see ref. 1). Phage middle-gene transcription is activated at 4–5 min into the lytic cycle by the SP01 gene *28* product[2,3], a regulatory protein that binds to *B. subtilis* RNA polymerase[4,5]. Enzyme containing the gene *28* protein asymmetrically transcribes phage middle genes *in vitro*[6-9]. Phage late-gene transcription is turned on 8–12 min after infection and this RNA synthesis seems to require the products of two SP01 regulatory genes called *33* and *34* (refs 2 and 3). As Fox shows in an accompanying article[10], genes *33* and *34* code for phage-induced subunits of the bacterial RNA polymerase, and Pero *et al.*[7] have shown that enzyme containing these phage-coded polypeptides preferentially synthesises late RNA *in vitro*. Pero *et al.*[6,7] have also identified a *B. subtilis* protein called δ that is associated with RNA polymerase from both uninfected and infected bacteria, and that markedly enhances the specificity of transcription by the phage-modified forms of RNA polymerase that copy middle and late genes *in vitro*.

To determine whether the subunits of RNA polymerase coded by genes *33* and *34* are directly responsible for the synthesis of late RNA *in vitro*, we have isolated these phage gene products in pure form free of the host subunits of RNA polymerase. By a reconstitution experiment we have shown that the gene *33* protein, the gene *34* protein and host δ protein act cooperatively to activate late gene transcription by core RNA polymerase.

Isolation of phage regulatory proteins

Highly purified RNA polymerase containing the protein products of genes *33* and *34* (formerly called subunits VI and V, respectively[6,7]) was isolated from phage SP01-infected cells of *B. subtilis* collected late in the lytic cycle (see legend to Fig. 1). The phage regulatory proteins were dissociated from core enzyme by denaturation in 6 M urea. To separate the proteins from the host subunits of polymerase, the denatured enzyme complex was applied to a phosphocellulose column equilibrated with buffer containing 6 M urea, and eluted with a linear gradient of KCl. The phage regulatory proteins were located by subjecting alternate fractions from the gradient elution to sodium dodecyl sulphate (SDS) polyacrylamide slab gel electrophoresis (Fig. 1*a*). Next, fractions 15–19 and 31–33 containing the phage regulatory proteins and some contaminating host polymerase subunits were subjected to gel filtration on Sephadex G-100 as a final purification step. SDS slab gel analysis showed that gel filtration had separated the proteins from each other and from the subunits of core polymerase (Fig. 1*b*). It is interesting that the phage proteins which have molecular weights of 24,000 and 13,500 (ref. 6), respectively, eluted from the Sephadex column at positions corresponding to ovalbumin (molecular weight 43,000) and to chymotrypsinogen (25,700). This could indicate either that the regulatory proteins have an unusual shape or that they form dimers in 6 M urea.

Purified gene *33* and gene *34* proteins were obtained by pooling fractions 40 to 46, and fractions 32 to 34, respectively, from the gel filtration column. Figure 2 shows that each pooled fraction apparently contained only a single highly purified polypeptide (Fig. 2*b* and *c*), corresponding in size to the regulatory proteins in phage-modified RNA polymerase (Fig. 2*a*). As further evidence for the identification of the purified regulatory proteins, a mixing experiment showed that the purified phage proteins of Fig. 2 comigrated during SDS gel electrophoresis with the radioactively-labelled protein

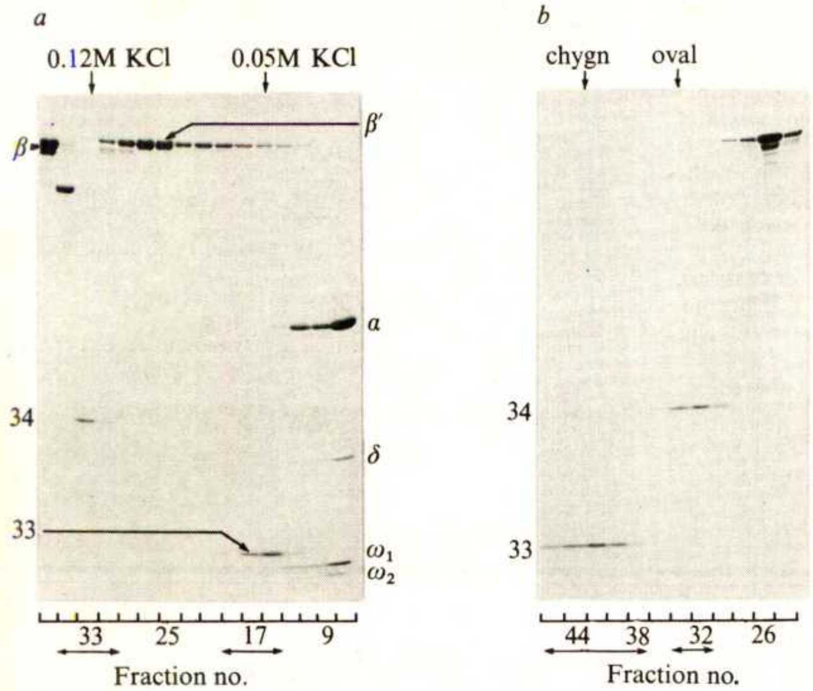

Fig. 1 Purification of the protein products of genes *33* and *34* by phosphocellulose chromatography and gel filtration in denaturing conditions. *B. subtilis* was infected with SP01 at a multiplicity of infection of 5 and collected 22 min after infection. RNA polymerase was purified from 80 g of infected cells through DEAE–Sephadex chromatography as described previously[11] except that the 2 M NaCl extraction during the phase partitioning step was omitted. One sixth of the DEAE–Sephadex-purified enzyme (5 mg), containing the subunits of core RNA polymerase[8] (β′, β, α, ω_1 and ω_2), δ protein, and the polypeptide products of genes *33* and *34*, was denatured by dialysis against buffer D (6 M urea, 0.05 M Tris, *p*H 8.0, 0.1 mM EDTA, 0.4 mM DTT and 0.05 M KCl). *a*, Denatured enzyme was then applied to a phospho-cellulose column (2 cm × 8 cm) equilibrated with buffer D and eluted with a linear gradient of 0.05–0.33 M KCl in buffer D. Fractions (3 ml) were collected and samples (25 µl) from every other fraction were subjected to electrophoresis on 25-cm-long slab gel containing SDS in a Tris–glycine buffer and a linear gradient of 7–15% acrylamide[12]. *b*, Fractions 15–19 and 31–33 containing the protein products of genes *33* and *34* were pooled, concentrated against Ficoll (Sigma) to a final volume of 1.5 ml, dialysed against buffer D for 2 h at 4 °C and then applied to a Sephadex G-100 column (0.9 cm × 100 cm) equilibrated with buffer D. Fractions (1 ml) were collected and samples (50 µl) from every other fraction were subjected to SDS slab gel electrophoresis. To renature the phage-coded proteins, gene *34* protein (in the pooled fractions 32–34) and gene *33* protein (in the pooled fractions 40–46) were mixed separately with core RNA polymerase (300 µg) from uninfected cells, concentrated threefold against Ficoll and then dialysed against the renaturation buffer (0.05 M Tris, *p*H 8.0, 0.1 mM EDTA, 25% glycerol, 8 mM DTT and 0.3 M KCl) for 3–6 h at 4 °C (ref. 13). The added core RNA polymerase which was inactivated on mixing with the regulatory proteins in buffer D did not regain significant activity (less than 0.2%) during renaturation. Thus the renatured regulatory protein fractions contained inactive core enzyme. The renatured regulatory proteins were stored at −20 °C until used in the reconstitution experiments. We were guided in the isolation and renaturation of the SP01-coded regulatory proteins by a discussion of the reconstitution of *E. coli* RNA polymerase by Zillig *et al.*[13].

products of genes *33* and *34* described in Fig. 1*a* of the accompanying article[10] (date not shown).

Finally, the two proteins which had been purified in the presence of 6 M urea were renatured in the presence of core RNA polymerase from uninfected cells (see legend to Fig. 1 for experimental details). In the conditions we used the presence of core enzyme was essential for recovery of the phage regulatory proteins in active form.

Strand selectivity of transcription

As a test of whether the renatured phage regulatory proteins would direct specific RNA synthesis, we asked whether these phage-coded polypeptides would cause selective transcription from the heavy (H) strand of native SP01 DNA, the strand from which late RNA is copied *in vivo*[6,14]. Figure 3*b* shows that in the presence of both phage proteins and host δ protein, purified core enzyme preferentially transcribed strand H of SP01 DNA (an H/L hybridisation ratio of 5.3). For comparison, core enzyme containing only added δ protein exhibited only a small preference for strand H (an H/L ratio of 1.9, Fig. 3*f*) while the original phage-modified polymerase plus added δ exhibited a strong preference for H strand DNA (an H/L

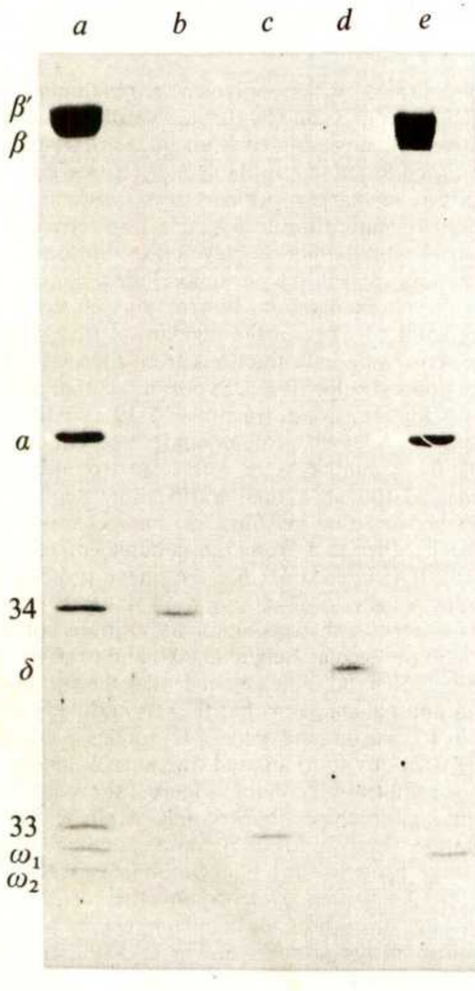

Fig. 2 SDS–polyacrylamide slab gel electrophoresis of RNA polymerase subunits from uninfected and SP01-infected *B. subtilis*. RNA polymerase containing the protein products of genes *33* and *34* was purified as described previously (enzyme C in ref. 6). Purification of the regulatory protein products of genes *33* and *34* is described in the legend to Fig. 1. Delta was isolated from uninfected cells as previously described[7] except that a DEAE–Sephadex column was used instead of a poly(C)–cellulose column to separate the δ subunit of RNA polymerase from the σ subunit; δ eluted at 0.5 M KCl while σ eluted at 0.25 M KCl. Purification of core RNA polymerase from uninfected cells has been described previously[11]. The purified proteins were subjected to electrophoresis as described in the legend to Fig. 1. *a*, RNA polymerase containing the protein products of genes *33* and *34*; *b*, gene *34* protein (fractions 32–34 from Fig. 1*b*); *c*, gene *33* protein (fractions 40–46 from Fig. 1*b*); *d*, δ protein; *e*, core RNA polymerase.

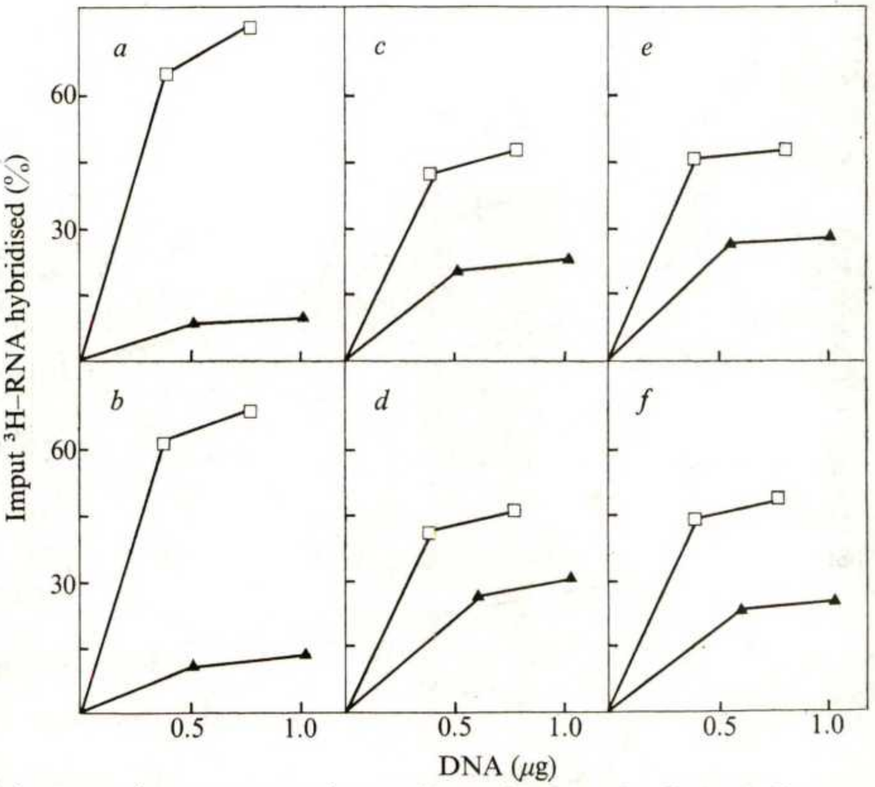

Fig. 3 Effect of phage regulatory proteins and host protein on strand selective transcription. Core RNA polymerase (13 μg) from uninfected cells (Fig. 2*e*) was mixed with the indicated combination of the following: 1.1 μg of renatured gene *33* protein, 1.5 μg of renatured gene *34* protein, 2.0 μg of δ protein, or mock renaturation reaction mixture to which no regulatory protein had been added. ^{3}H-RNA was synthesised *in vitro* as described previously[6] except that the reaction mixtures (0.5 ml) contained 0.025 M KCl, 0.9 mg anti-sigma gamma globulin[15] and were incubated at 32 °C for 30 min. (The anti-sigma gamma globulin was necessary to inactivate traces of σ that contaminated the core RNA polymerase and that severely interfered with the transcriptional specificity of the reconstituted enzymes.) Hybridisation of RNA and preparation of DNA strands were as described previously[6]. Hybridisation reactions contained the indicated amounts of H strand (□) and L strand (▲) SP01 DNA and the following ^{3}H-RNAs (representing about 5% of the product of the *in vitro* RNA synthesis reactions) in 125 μl of 2×SSC. *a*, RNA synthesised by RNA polymerase (6.0 μg) containing the protein products of genes *33* and *34* together with host δ purified as described in the legend to Fig. 1 (input 8,960 c.p.m.; background 490 c.p.m.). *b*, RNA synthesised by core polymerase+renatured gene *33* protein+renatured gene *34* protein+δ protein (input 9,180 c.p.m.; background 250 c.p.m.). *c*, RNA synthesised by core polymerase+renatured gene *33* protein+δ protein (input 10,510 c.p.m.; background 250 c.p.m.). *d*, RNA synthesised by core polymerase+renatured gene *34* protein+δ protein (input 7,250 c.p.m.; background 130 c.p.m.). *e*, RNA synthesised by core polymerase+renatured gene *33* protein+renatured gene *34* protein (input 15,830 c.p.m.; background 340 c.p.m.). *f*, RNA synthesised by core polymerase+δ protein+mock renaturation reaction mixture (input 7,010 c.p.m.; background 200 c.p.m.).

ratio of 8.4, Fig. 3*a*). Specific RNA synthesis by the reconstituted enzyme required both the protein products of genes *33* and *34*, for the strand selectivity of transcription in the absence of either regulatory protein (H/L ratio of 2.0 and 1.8, Fig. 3*c* and *d*) was not measurably higher than in the absence of both regulatory gene products (H/L = 1.9, Fig. 3*f*). Also, as expected from our previous findings[7], specific transcription by reconstituted enzyme required host δ protein in addition to the phage regulatory proteins; the strand selectivity of transcription by reconstituted enzyme lacking added δ (an H/L ratio of 1.9, Fig. 3*e*) was only slightly higher than that for core enzyme alone (an H/L of 1.3, ref. 6 and data not shown). Thus, the reconstitution of enzyme directing strand selective transcription required the addition of both regulatory proteins and host δ factor to core polymerase.

As an independent test of the asymmetry of transcription we measured the formation of RNA·RNA duplexes between labelled RNA synthesised *in vitro* and unlabelled early, middle and late RNAs isolated from phage-infected cells. The percentage of ^{3}H-RNA that annealed to the *in vivo* synthesised messenger RNAs was taken as a measure of the proportion of *in vitro* generated RNA representing anti-messenger sequences. As expected, a large percentage of the RNA synthesised by core RNA polymerase contained anti-mRNA sequences (line 1, Table 1). Similarly, RNA synthesised by partially reconstituted enzyme containing core polymerase and host δ but lacking the products of either gene *34* (line 2, Table 1) or gene *33* (line 3, Table 1) contained high levels of anti-mRNA. Likewise, if both phage gene products were included but host δ factor was omitted, a large proportion of the *in vitro* synthesised RNA contained anti-messenger sequences (line 4, Table 1). In contrast, very little anti-mRNA was generated by the fully reconstituted enzyme containing both phage-coded regulatory proteins and host δ factor (line 5, Table 1). For comparison, core polymerase plus host σ factor also synthesised low levels of anti-messenger (line 6, Table 1). Thus, the genes *33* and *34* proteins and host δ protein act cooperatively to catalyse asymmetric transcription of native SP01 DNA.

Synthesis of late RNA

Hybridisation–competition experiments indicated that core enzyme that had been reconstituted with the protein products of genes *33* and *34* and host δ factor preferentially synthesised

Table 1 Anti-mRNA synthesised *in vitro*

Enzyme	% ^{3}H-RNA forming duplexes with *in vivo* RNAs Early RNA	 Middle RNA	 Late RNA
Core polymerase	32	33	44
Core polymerase+δ+ gene *33* protein	31	30	40
Core polymerase+δ+ gene *34* protein	32	31	43
Core polymerase+ gene *33* protein+ gene *34* protein	41	34	34
Core polymerase+δ+ gene *33* protein+ gene *34* protein	12	9	13
Core polymerase+σ	6	7	15

RNA synthesis *in vitro* was as described in the legend to Fig. 3 except that no anti-sigma gamma globulin was included in the experiment of line 6. Early RNA was isolated from bacteria treated with chloramphenicol (150 μg ml^{-1}) before infection; middle RNA was isolated from bacteria collected 25 min after infection by a mutant phage (*sus*F4) blocked in the synthesis of late RNA[2]; and late RNA was isolated from cells collected 25 min after infection by wild-type SP01. Unlabelled RNA was prepared as previously described[7]. The RNA·RNA annealing reactions contained about 10 ng of ^{3}H-RNA (800 c.p.m. ng^{-1}) synthesisied *in vitro* by the indicated enzyme and about 0.15 mg of the indicated unlabelled RNA in a total volume of 150 μl of 2×SSC. The reactions were incubated at 70 °C for 3 h, chilled and incubated with RNase A (20 μg) and RNase T1 (20 U) in 1 ml of 2×SSC for 1 h at 35 °C. RNase resistant material was precipitated with 5% trichloroacetic acid.

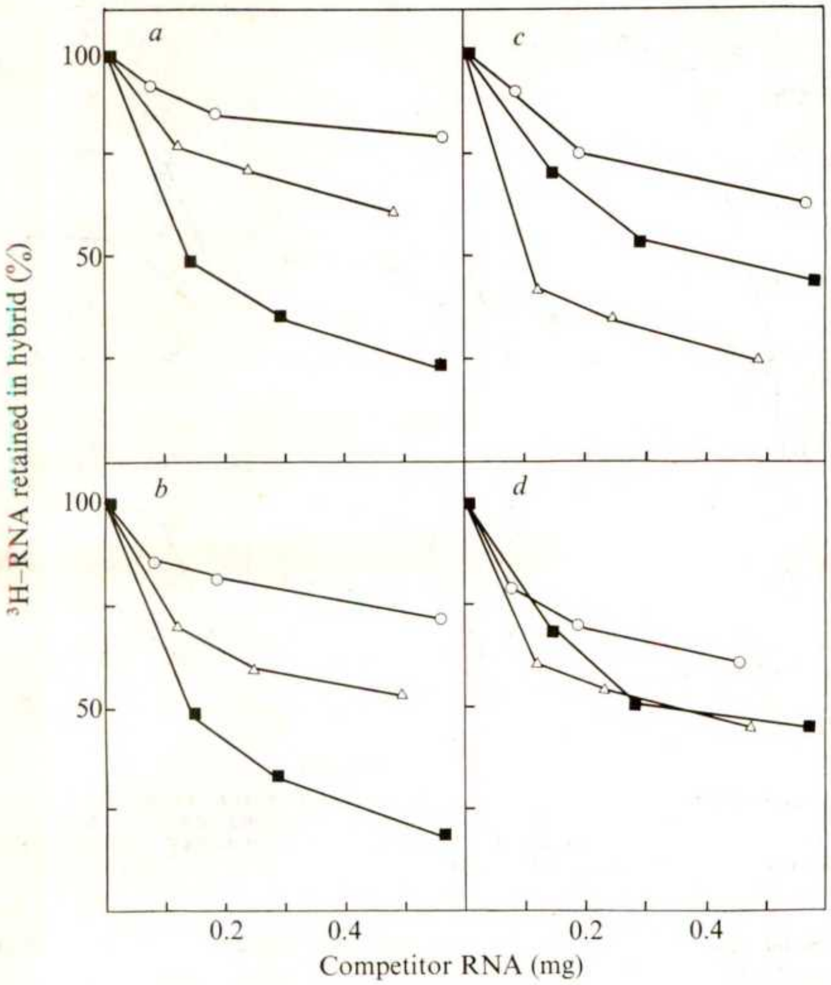

Fig. 4 Hybridisation competition of *in vitro* synthesised ^{3}H-RNAs. RNA was synthesised and hybridisations were performed as described in the legend to Fig. 3 except that the hybridisation reaction was incubated for 3 h at 68 °C. Hybridisation reactions contained 2.5 μg of denatured SP01 DNA, the indicated amounts of unlabelled early (○), middle (△) or late (■) competitor RNAs prepared as described in the legend to Table 1, and the following, *in vitro* synthesised ^{3}H-RNA (representing about 5% of the product in the reactions listed below) in a total volume of 200 μl of 2×SSC. *a*, RNA synthesised by RNA polymerase (6.0 μg) containing the protein products of genes *33* and *34* together with host δ; 50% of the input RNA (8,440 c.p.m.) hybridised in the absence of competitor. *b*, RNA synthesised by core polymerase (13 μg)+renatured gene *33* protein (1.0 μg)+renatured gene *34* protein (1.5 μg)+δ protein (2.0 μg); 51% of the input RNA (9,570) hybridised in the absence of competitor. *c*, RNA synthesised by RNA polymerase (10 μg) containing the gene *28* protein (enzyme B of ref. 7)+δ protein (1.2 μg); 50% of the input RNA (9,600 c.p.m.) hybridised in the absence of competitor. *d*, RNA synthesised by core polymerase (13 μg)+δ (2.0 μg)+mock renaturation reaction mixture; 52% of the input RNA (7,150 c.p.m.) hybridised in the absence of competitor. For each hybridisation a background of less than 7% of the input radioactivity was subtracted.

late RNA sequences. ^{3}H-RNA synthesised *in vitro* by reconstituted enzyme was annealed to denatured SP01 DNA in the presence of unlabelled competitor RNAs containing predominantly early, middle or late classes of RNA. To be sure that the middle RNA did not contain late sequences, this competitor was isolated from bacteria that had been infected with a mutant blocked in late gene expression (see legend to Table 1). (Similar competition results, however, were obtained with competitor RNA isolated at a middle time after infection with wild-type SP01 (unpublished results and ref. 7).) Figure 4*b* shows that the hybridisation of RNA synthesised *in vitro* by the reconstituted enzyme was more effectively inhibited by the late RNA competitor than by the middle or early RNA competitors. This pattern of competition was similar to that obtained for the hybridisation of RNA synthesised by the original phage-modified polymerase containing the protein products of genes *33* and *34* together with δ protein (Fig. 4*a*). In contrast, the hybridisation of RNA synthesised *in vitro* by polymerase containing the gene *28* protein plus δ factor was more effectively inhibited by middle RNA competitor than by late or early RNA competitors (Fig. 4*c*). As a control, the hybridisation of the symmetrical RNA generated by core polymerase plus δ was not preferentially inhibited by the late RNA competitor (Fig. 4*d*). Also, analogous hybridisation experiments indicated that partially reconstituted enzymes lacking either the gene *33* product, the gene *34* product or δ protein did not preferentially generate late RNA sequences. Thus, like the strand selectivity of transcription, the preferential transcription of SP01 late genes *in vitro* required the combined effects of both phage-coded regulatory proteins and host δ factor.

Gene products control transcription

Our reconstitution experiments establish that the products of genes *33* and *34* are directly responsible for promoting the asymmetrical transcription of phage SP01 late genes *in vitro*. Since the protein products of genes *33* and *34* were isolated in pure form, we further conclude that these two regulatory proteins are apparently the only SP01-coded proteins required for the synthesis of late RNA *in vitro*. We have not, however, determined whether these two proteins are sufficient to direct the transcription of all SP01 late genes or only a subset of phage late sequences. As expected from an earlier study[7], the reconstitution experiments also show that the specific transcription of phage late genes required host protein δ but not the σ subunit of RNA polymerase.

The synergistic effect of the protein products of genes *33* and *34* on late gene transcription *in vitro* is in apparent agreement with earlier genetic studies indicating that a mutation in either gene *33* or gene *34* alone is sufficient to block late RNA synthesis *in vivo*[2,3]. The genetic experiments do not, however, necessarily predict that both regulatory proteins are simultaneously required for the expression of late genes *in vivo*. For example, as discussed by Fox[10], it is possible, though unlikely, that the gene *33* protein serves only to activate regulatory gene *34* and that the gene *34* protein alone is sufficient to direct late RNA synthesis *in vivo*. The *in vitro* requirement for both regulatory proteins for asymmetric transcription of late genes casts doubt on such a model.

It is likely that the SP01 gene *28* protein also interacts with *B. subtilis* RNA polymerase to activate middle-gene expression. Fox *et al.*[4] have shown that gene *28* codes for a phage-induced subunit of polymerase, and Pero *et al.*[6,7] and Duffy and Geiduschek[8] have shown that RNA polymerase containing the gene *28* product asymmetrically transcribes phage middle genes *in vitro*. In further support for the idea that a phage-coded protein confers specificity for middle genes on RNA polymerase, Duffy *et al.*[16] have partially purified a fraction from crude extracts of SP01-infected cells that causes preferential synthesis of middle RNA by core enzyme. This fraction contained a phage-induced protein similar in size to the gene *28* product that was able to bind to core RNA polymerase from uninfected cells. Petrusek *et al.*[17] have attempted to isolate this transcriptional determinant by denaturing in urea an RNA polymerase fraction containing several phage-induced proteins, including polypeptides that apparently correspond to the products of genes *28*, *33* and *34*. Unfortunately, in both cases the protein presumed to direct middle-gene transcription was only one component of a partially purified fraction containing several proteins and it was not excluded that another polypeptide had been responsible for conferring transcriptional specificity on the core enzyme. Indeed, a new protein species has been identified that is apparently distinct from the product of gene *28* and that promotes asymmetric transcription of phage middle genes *in vitro*[18]. Proof that the gene *28* protein itself directly influences the transcriptional specificity of RNA polymerase therefore awaits the isolation of this phage-coded regulatory protein in pure form.

In summary, our findings establish that two phage-coded subunits of RNA polymerase are directly responsible for promoting specific gene transcription. How do the protein products of genes *33* and *34* work? As they influence transcription in the absence of the host σ factor, we suppose that they cause RNA polymerase to initiate transcription at specific promoter sites for phage late genes. A test of this idea now requires the isolation of fragments of SP01 DNA specifying individual late gene transcripts.

We thank Jane Nelson for preparing the DNA strands and competitor RNAs, R. Losick, T. Fox and W. Gilbert for helpful discussions, and R. Losick for help with the manuscript. The yeast amber suppressor, SUP5-***a***, *was previously shown to cause the insertion of tyrosine at the sites of UAG nonsense codons. Nucleotide sequencing established that this* SUP5-***a*** *suppressor specifies a mutant tyrosine transfer RNA (tRNA) which has the anticodon CΨA instead of the normal GΨA, an alteration identical to that found in the tyrosine-inserting amber suppressor from* Escherichia coli.

THE three codons UAG (amber), UAA (ochre) and UGA (opal) serve as signals for polypeptide chain termination during messenger RNA translation in various prokaryotic and eukaryotic organisms[1–9]. When one of these codons arises internally in a structural gene as a result of mutation, the gene product is an incomplete polypeptide. Such nonsense mutations can be reverted by an unlinked suppressor mutation, which alters one of the components required for protein synthesis and facilitates the formation of a completed polypeptide through the insertion of an amino acid at the position of the nonsense codon. The most extensively studied suppressors arise by mutation of the structural genes for tRNA although other suppressors can arise by mutation of genes controlling tRNA modification enzymes or ribosomal proteins (for review see refs 10–12). Sequencing of suppressor tRNAs has shown that the base changes giving rise to the suppressor function can occur at the anticodon[13–16] and in other regions of the tRNA structure[17].

The eukaryotic yeast *Saccharomyces cerevisiae* can form nonsense suppressors similar to those of *E. coli* (for review see ref. 18). Several of these nonsense suppressors have been characterised by their action on *iso*-1-cytochrome *c* mutants which contain defined ochre (UAA) and amber (UAG) mutations[19,20]. In contrast to any of the *E. coli* suppressors, a major class of suppressors from yeast acts specifically on UAA and not UAG codons. Whereas bacterial ochre suppressors recognise both UAA and UAG codons, suppressors acting specifically on only UAG codons are found in both *E. coli* and yeast. The amino acids inserted by the yeast suppressors have been determined from protein analysis of *iso*-1-cytochrome *c* in suppressed mutants. So far tyrosine, serine and leucine-inserting suppressors have been identified (refs 21–25, 45). Studies of translation *in vitro* of mRNA containing nonsense codons have shown that the suppressor activities of at least some of the yeast suppressors are due to altered tRNAs[26,27]. Such yeast suppressor tRNAs may have a potential application in methods for the selection and biochemical characterisation[28,46] of nonsense mutants of mammalian cells and their viruses. But although the *in vitro* studies showed that suppression is mediated by tRNAs, the results did not indicate whether the suppressor mutations caused alterations in either the nucleotide sequences of tRNAs or the enzymes that modify them. Also the tRNA giving rise to a suppressor cannot always be identified from the amino acid inserted at the nonsense codon. This is true in the case of the recessive-lethal glutamine and trytophan-inserting Su 7 suppressor of *E. coli*, which is derived from trytophan tRNA by a single base substitution in the anticodon[16,29,30] as well as for the glutamine-mischarging mutants derived from *E. coli*, Su$^{+}_{3}$ tRNA$^{\text{Tyr}}$ (ref. 34).

†Present address: Imperial Cancer Research Fund Laboratories, Lincolns Inn Fields, London WC2 3PX, UK.

We present here direct evidence that at least one yeast suppressor arose by the mutational alteration of the nucleotide sequence of a tRNA, and we report the nucleotide change in this suppressor tRNA. The suppressor examined in this study, *SUP5*-**a**, is typical of one of the eight distinct suppressors (*SUP2*-**a**, *SUP3*-**a**, *SUP4*-**a**, *SUP5*-**a**, *SUP6*-**a**, *SUP7*-**a**, *SUP8*-**a** and *SUP11*-**a**) that cause insertion of tyrosine at UAG sites[22,24]. In addition, a parallel series of allelic suppressors, *SUP2*-**o**, *SUP3*-**o**, and so on, causes the insertion of tyrosine at UAA sites[21]. Nucleotide sequencing established that *SUP5*-**a** determines a mutant form of tyrosine tRNA which has the anticodon CΨA instead of the normal GΨA. This altered anticodon was observed whether the amber suppressor arose from the wild-type gene or from the UAA suppressor *SUP5*-**o.** With our techniques we were unable to reveal the tRNA alteration associated with the *SUP5*-**o** suppressor. We were also unable to detect altered tRNA when the *SUP5*-**a** suppressor mutated to the less efficient *SUP5*-**a**→**a**^{1} suppressor[32].

Minor tRNA$^{\text{Tyr}}$ with altered anticodon in amber-suppressing strains

Only one tyrosine tRNA is found in *S. cerevisiae* and its nucleotide sequence is known[33]. If the tyrosine-inserting suppressors of this organism are the products of single-base substitutions of tRNA$^{\text{Tyr}}$ genes, such a suppressor tyrosine tRNA would be expected to copurify with the bulk of the tyrosine tRNA. Eight loci can mutate to these suppressors. Therefore when one of them mutates, the product of the mutated gene should be a minor component of the total tRNA$^{\text{Tyr}}$. This can be investigated by sequencing tRNA$^{\text{Tyr}}$ associated with strains possessing these suppressors, provided this species can be isolated to a high degree of purity. We have found that the two-dimensional electrophoretic separation of tRNAs on polyacrylamide gel[37] can be used routinely to isolate small amounts of extremely pure ^{32}P-tRNA$^{\text{Tyr}}$ from yeast cultures (Fig. 1). The relative positioning of different tRNAs on the gels was sufficiently reproducible for the tRNA$^{\text{Tyr}}$ spot (arrowed in Fig. 1) to be identified from the spot pattern, once it had initially been characterised on the basis of its fingerprint. The sequence analyses described here were carried out on the purified total tRNA$^{\text{Tyr}}$ of the strains listed in Table 1.

S. cerevisiae strain L-133, with the highly efficient tyrosine-inserting amber suppressor *SUP5*-**a**[24,32], was examined for the presence of an altered tRNA$^{\text{Tyr}}$. As a control, tRNA$^{\text{Tyr}}$ was also

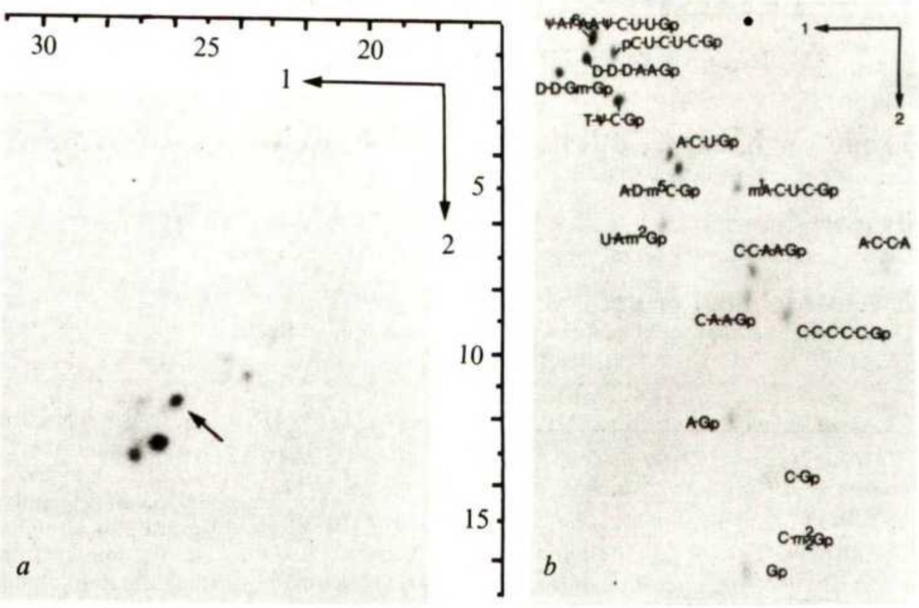

Fig. 1 Purification of tyrosine tRNA from yeast. Cultures (50 ml) were grown at 30 °C in nutrient low phosphate medium[34] containing 6 mCi of carrier-free ^{32}P-orthophosphate. Immediately before collection of each culture, a few cells were plated so that the proportion retaining the original suppressor at the time of collection could be determined subsequently by measuring suppression of auxotropic and *iso*-1-cytochrome *c* nonsense mutants. Levels of *iso*-1-cytochrome *c* were used to distinguish between amber suppressors with different efficiencies of suppression. This was necessary because of the instability of suppressors and their tendency to mutate to less efficient forms[32]. Only cultures in which more than 90% of the cells retained the phenotype of the original suppressor were retained for the analyses. After the rest of the cells had been collected by centrifugation, RNA was extracted from the cell pellets[34], precipitated with ethanol and lyophilised. RNA samples were then dissolved in small volumes of 0.35 M NaCl, 0.01 M MgCl$_2$, 0.01 M sodium acetate, *p*H 5.0, and applied to 1 cm × 8 cm columns of benzoylated DEAE–cellulose previously equilibrated with the same buffer. tRNA was eluted in two consecutive steps, by applying to the columns first: 0.85 M NaCl, 0.01 M MgCl$_2$, 0.01 M sodium acetate, *p*H 5.0; and later: 1.0 M NaCl, 0.01 M MgCl$_2$, 20% ethanol, 0.01 M sodium acetate, *p*H 5.0. The tRNA fraction eluted by the ethanol-containing buffer was concentrated by ethanol precipitation, lyophilised and redissolved in 0.035 ml of gel sample buffer (60% sucrose, 4 M urea, 0.1 M sodium acetate, *p*H 5.0, 1% xylene cyanol FF). It was then separated by two-dimensional gel electrophoresis[35]. tRNA spots were located by autoradiography of the wet gels, extracted[34] and individual tRNA species were identified from their fingerprints. *a*, Autoradiogram of a two-dimensional gel. The scales indicate the distances of migration (cm) in the first dimension (1) 10% gel and second dimension (2) 20% gel. The tRNA$^{\text{Tyr}}$ spot is indicated by an arrow. *b*, Fingerprint of a ribonuclease T$_1$ digest of tRNA$^{\text{Tyr}}$. The RNA sample was purified on a two-dimensional gel, and individual oligonucleotides on the fingerprint are identified by their sequences. The first (1) and second (2) dimensions of electrophoretic separation[38] are indicated.

Table 1 Yeast strains

Strain no.	Abbreviated genotype	Derived from:	Suppresses	Suppressor inserts	Efficiency	Anticodon of tyrosine tRNA product of *SUP5* locus
SL210-3A	*sup*$^+$	—	None	—	—	GΨA
L-133	*SUP5*-**a**	*sup*$^+$	UAG	Tyrosine	high	GΨA→CΨA
SL171-2C	*SUP5*-**o**	*sup*$^+$	UAA	Tyrosine	high	GΨA→?
L-58	*SUP5*-**o**→**a**	*SUP5*-**o**	UAG	Not determined	high	?→CΨA
L-133a	*SUP5*-**a**→**a′**	*SUP5*-**a**	UAG	Not determined	low	Unknown

examined for the non-suppressing *sup*$^+$ strain (SL210–3A) from which the *SUP5*-**a** mutant had been derived. No difference between the total tRNA$^{\mathrm{Tyr}}$ of these two strains could be discerned when T$_1$ or pancreatic ribonuclease digests were fingerprinted in two dimensions, using electrophoresis on cellulose acetate at *p*H 3.5 in the first dimension and on DEAE paper in 7% formic acid[36] in the second dimension, as in Fig 1*b*. If, however, T$_1$ ribonuclease digests were separated by homochromatography[36] in the second dimension, so as to effect better separation of the large oligonucleotides, a distinct difference in the fingerprints was apparent. Figure 2*a* shows a fingerprint of *sup*$^+$ tRNA$^{\mathrm{Tyr}}$ digested with T$_1$ ribonuclease, and Fig. 2*b* and *c* shows the corresponding fingerprints of total rRNA$^{\mathrm{Tyr}}$ from two different *SUP5*-**a** cultures. A large oligonucleotide (marked C in Fig. 2*b* and *c*) is present in the T$_1$ ribonuclease digest of the *SUP5*-**a** tRNA$^{\mathrm{Tyr}}$ but is absent from the corresponding digest of the *sup*$^+$ tRNA$^{\mathrm{Tyr}}$. Since this fragment is not one of the normal digestion products of yeast tRNA$^{\mathrm{Tyr}}$, its nucleotide sequence was determined. It was degraded by pancreatic ribonuclease (Fig. 3) to give Ai^{6}AAΨp, ACp, Gp, Cp, Ψp, and Up. Also, after reacting the U, G and Ψ residues with carbodiimide reagent and analysing the products of subsequent pancreatic ribonuclease digestion[36], it was possible to show that this fragment contained the sequences (C)UC and (C)UUG (results not shown). Partial digestion with ribonuclease U$_2$ gave a series of fragments shown separated in Fig. 3, which were identified from their base compositions. The data obtained were only consistent with the nucleotide sequence: ACUCΨAi^{6}AAΨCUUGp. Figure 4 shows that this oligonucleotide is derived from a tRNA$^{\mathrm{Tyr}}$ with anticodon CΨA. The species with such an anticodon would be expected to function as a UAG suppressor. Minor nucleotide analyses carried out in conjunction with the sequence analysis of fragment C showed that the second anticodon base of the suppressor tyrosine tRNA is pseudouridine, as in the wild-type tRNA$^{\mathrm{Tyr}}$. The weak intensity of the mutant anticodon spot C (Fig. 2*b* and *c*) indicates that only 5–8% of the total tRNA$^{\mathrm{Tyr}}$ from the *SUP5*-**a** strain existed in the form of this amber suppressor species, a level that is consistent with this species being the product of one of the eight genes for tyrosine tRNA. A UAG-specific suppressor can therefore be generated in both *E. coli*[13] and yeast by mutation of the first base of the tyrosine tRNA anticodon.

The tRNA$^{\mathrm{Tyr}}$ from other amber suppressor alleles of *SUP5* was also examined. The *SUP5*-**o**→**a** allele was obtained[24] by mutation of the *SUP5*-**o** UAA suppressor, in contrast to the *SUP5*-**a** allele which was obtained directly from the *sup*$^+$ wild type. But *SUP5*-**o**→**a** and *SUP5*-**a** are phenotypically indistinguishable and the sequence analyses of their tRNA$^{\mathrm{Tyr}}$ (Figs 2*e* and 3*c* and *f*) indicate that they are identical.

Since we have shown that these suppressors arise by mutation of the tyrosine tRNA anticodon, it is possible to study the structure and function of this species, as has been done with *E. coli* and bacteriophage tRNA suppressors. It has been shown that second base changes in the yeast amber suppressor tRNA$^{\mathrm{Tyr}}$ result in the suppressor functioning at a lower efficiency[32]. We have analysed one of these suppressors, *SUP5*-**a**→**a**^{1} in strain L-133a which arose by an intragenic mutation of *SUP5*-**a** in L-133. In the fingerprint of tRNA$^{\mathrm{Tyr}}$ from *SUP5* **a**→**a′** (Fig. 2*f*), the anticodon fragment of the amber suppressor tRNA$^{\mathrm{Tyr}}$ was either absent or present at an undetectable level. It is possible that the second site mutation of the *SUP5*-**a**→**a′** locus causes a reduced synthesis of suppressor tRNA, in much the same way as certain mutations of the *su*$_3^+$ tRNA$^{\mathrm{Tyr}}$ gene of *E. coli* impair tRNA maturation[37].

Lack of identification of UAA-specific suppressor

Unlike bacterial ochre suppressors which recognise both UAA and UAG codons, yeast UAA suppressors act only on UAA

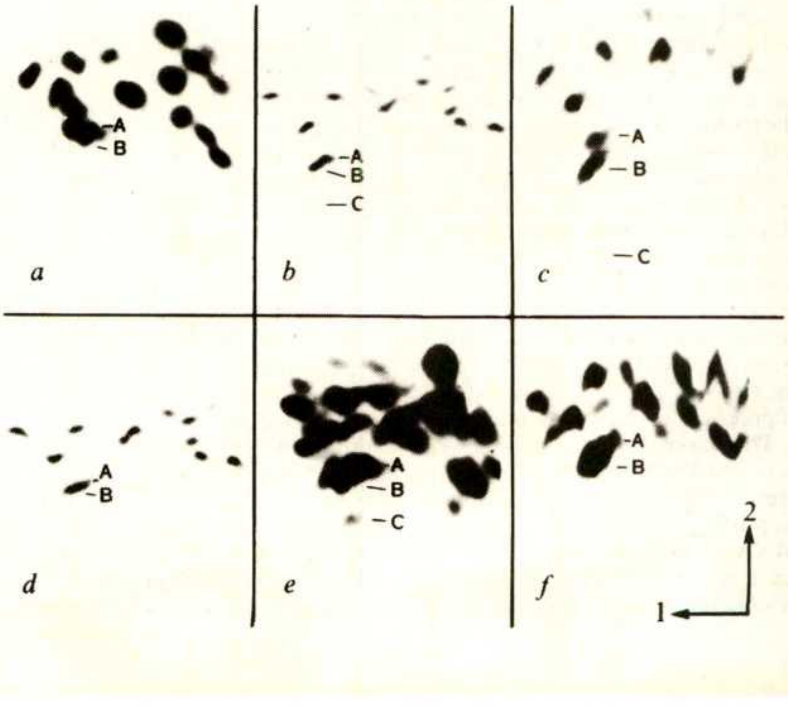

Fig. 2 T$_1$ ribonuclease digests of tyrosine tRNA isolated from: *a*, *SUP*$^+$ (SL210-3A); *b* and *c*, two different cultures of *SUP5*-**a** (L-133); *d*, *SUP5*-**o** (SL171-2C); *e*, *SUP5*-**o**→**a** (L-58), and *f*, *SUP5*-**a**→**a′** (L-133a). Oligonucleotide separation was by electrophoresis on cellulose acetate in the first dimension (1) and ascending chromatography on DEAE–cellulose thin layers in the second dimension (2) using a 3% dialysed homomixture[38]. A and B identify respectively the oligonucleotides pCUCUGp and ΨAi^{6}AAΨCUUGp. C, ACUCΨAi^{6}AAΨCUUGp, is the anticodon fragment of the amber suppressor tRNA$^{\mathrm{Tyr}}$, present only in fingerprints (*b*), (*c*) and (*e*). Other differences between the fingerprints are due to differences in the resolving power of homomixtures and fluctuations in the extent to which T$_1$ ribonuclease has cleaved the fragment Cm$^2_2$GCAAGp into Cm$^2_2$G>p and CAAGp.

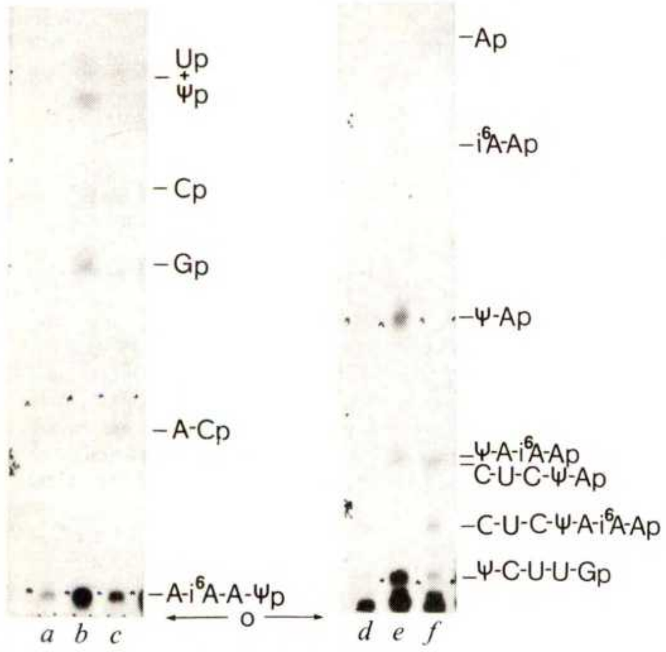

Fig. 3 Pancreatic and U$_2$ ribonuclease digests of the anticodon oligonucleotides of the UAG suppressor tRNA$^{\mathrm{Tyr}}$. *a* and *c*, Pancreatic ribonuclease digests of ACUCΨAi^{6}AAΨCUUGp, the anticodon loop fragments of the amber suppressor tRNA$^{\mathrm{Tyr}}$, derived, respectively, from strains *SUP5*-**a** and *SUP5*-**o**→**a**. *b*, Marker digest of ΨAi^{6}AAΨCUUGp. Separation was by electrophoresis, 1 kV for 3 h, on DEAE paper at *p*H 3.5. *d* and *f*, U$_2$ ribonuclease digests of the anticodon loop fragment of amber suppressor tRNA$^{\mathrm{Tyr}}$ derived from *SUP5*-**a** and *SUP5*-**o**→**a**, respectively. *e*, Marker U$_2$ digest, of ΨAi^{6}AAΨCUUGp. Digestion was with 0.05 ml of U$_2$ ribonuclease (0.1 U ml^{-1}), 0.05 M sodium acetate, *p*H 4.5, for 4 h at 37 °C, and separation was by electrophoresis, 1 kV for 6 h on DEAE paper in 7% formic acid.

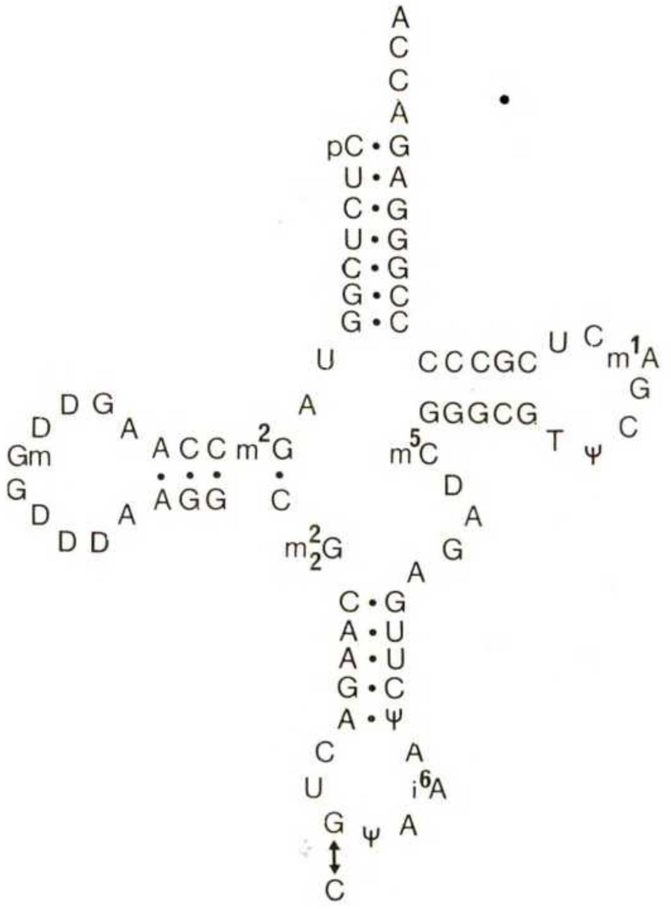
and not on UAG codons. The only *E. coli* ochre suppressor which has been sequenced is the tRNAoc$^{\mathrm{Tyr}}$. This species has the anticodon U*UA[14,38] and should therefore decode both UAA and UAC to UAG according to the 'wobble' theory of codon-anticodon recognition[39]. A mutant suppressor glutamine tRNA of phage T$_4$, with NUA anticodon, also recognises both UAA and UAG[15,40]. There have been two proposals to explain how an ochre suppressor tRNA$^{\mathrm{Tyr}}$ of yeast might be able to decode UAA but not UAG. According to the first hypothesis[41], the anticodon is presumed to be IΨA (topaz) obtained by mutation of the anticodon to AUA, followed by enzymatic modification, thus giving a tRNA which should translate UAA in addition to the two normal tyrosine codons. The second hypothesis[21] is that the mutant tRNA$^{\mathrm{Tyr}}$ has the anticodon SΨA (sepia) where S is 2-thio-5-carboxymethyluridine methyl ester. This modified nucleoside has been identified as the first anticodon base in tRNA$_3^{\mathrm{Glu}}$ (ref. 42) and tRNA$_2^{\mathrm{Lys}}$ (refs 43, 44) from yeast. In this position it pairs preferentially with adenosine rather than guanosine in the third position of a codon. A third possibility might be that a weak recognition of UAA by tRNA$^{\mathrm{Tyr}}$ is enhanced by a base change outside the anticodon. This is known to be the case for UGA recognition by a suppressor tRNA$^{\mathrm{Trp}}$ of *E. coli*[17]. An anticodon change, however, is much more probable in view of the demonstration that tyrosine-inserting ochre suppressors of yeast can mutate to allelic amber suppressors.

To explore these possibilities, we fingerprinted tRNA$^{\mathrm{Tyr}}$ from strain SL171-2C which carries a tyrosine-inserting ochre suppressor, *SUP5*-**o**, that is allelic to the amber suppressor *SUP5*-**a**. According to the second hypothesis, the UAA suppressing tRNA$^{\mathrm{Tyr}}$ should yield the fragment ACUSΨAi^{6}AAΨCUUGp on digestion with T$_1$ ribonuclease. This oligonucleotide differs in only one base from the anticodon fragment of the *SUP5*-**a** tRNA$^{\mathrm{Tyr}}$. Assuming the unstable S nucleoside does not produce anomalous behaviour, such an oligonucleotide should occupy almost the same position on the fingerprints as the amber suppressor anticodon at spot C. In the fingerprint of the *SUP5*-**o** tRNA$^{\mathrm{Tyr}}$ (Fig. 2*d*) no spot could be seen in this position. If, however, the ochre suppressor has an IΨA anticodon, then the sole difference between a T$_1$ ribonuclease digest of this species and that of normal tRNA$^{\mathrm{Tyr}}$ will be the presence of ACUIp in place of ACUGp (Fig. 1*b*), since the enzyme cleaves polynucleotides after both G and I. Because of technical difficulties in identifying a small amount of a ^{32}P-labelled minor nucleotide from a very small fraction of the *SUP5*-**o** tRNA$^{\mathrm{Tyr}}$, we did not pursue this analysis further.

Interpretation

Nucleotide sequencing established that the yeast amber suppressor *SUP5*-**a** determines a mutant form of tRNA$^{\mathrm{Tyr}}$ which has the anticodon CΨA instead of the normal GΨA. This mutationally altered anticodon is consistent with amber suppressibility according to the wobble hypothesis and it corresponds to the anticodon of a tRNA$^{\mathrm{Tyr}}$ amber suppressor of *E. coli*. Although we were unable to detect the nucleotide changes of tRNA$^{\mathrm{Tyr}}$ associated with the UAA suppressor *SUP5*-**o**, the amber suppressor anticodon was clearly absent. The nature of the anticodon in the *SUP5*-**a** tRNA$^{\mathrm{Tyr}}$ could be inferred from the observation that the tRNA$^{\mathrm{Tyr}}$ corresponding to the amber suppressor *SUP5*-**o**→**a**, which was derived by a single-step mutation from *SUP5*-**o**, seemed to have an identical sequence to *SUP5*-**o** tRNA$^{\mathrm{Tyr}}$ which was derived by a single-step mutation from the wild-type gene. Assuming that the mutations occurred by single-base changes, the simplest interpretation of these results is that the UAA suppressor is a

Fig. 4 Primary structure of yeast tRNA$^{\mathrm{Tyr}}$ (ref. 35) showing the anticodon base substitution present in the amber suppressor tRNA$^{\mathrm{Tyr}}$ species.



tRNA^{Tyr} having an alteration of the first base in the anticodon, although the base in question has not been identified.

Systematic approach to the correction of intonation in wind instruments

Richard A. Smith

Boosey and Hawkes Ltd, Edgware, Middlesex, UK and Department of Physics, Southampton University

Geoffrey J. Daniell

Department of Physics, Southampton University, Southampton SO9 5NH, UK

The effect of perturbations in the bore diameter on the intonation of wind instruments is investigated. From measurements of the bore and the amplitude of the standing waves, a modified bore shape is calculated to give any desired correction in intonation.

MUSICAL instruments have evolved over the centuries very much by trial and error. In spite of scientific investigation, many undetermined factors critically affect the performance of instruments, and empirical methods of design are still necessary. Some features, however, are easily amenable to quantitative treatment, and we present here the results of some calculations and experiments on improving the intonation and tone colour of the trumpet.

All brass instruments have acoustical and mechanical inadequacies for which most players automatically compensate[1]. To the average listener an instrument may sound perfectly in tune but this largely results from the competence of the player who may be able to 'lip' a note by ± 1 semitone, usually at the expense of tone colour. Similarly, the intonation of inexperienced players tends to be more affected by the deficiencies of their instruments.

The frequency of a note produced by a trumpet is determined by a complex interaction between the vibrating air column in the instrument and the player's lips. It is also affected by acoustical feedback to the player's ears, and differences of more than 10 cents (1 cent = 0.01 tempered semitone) occur when different players use the same instrument. The frequency is, however, always very close to a resonance frequency of the air column in the trumpet.

The necessity of first eliminating the contribution of the individual player to the intonation has been recognised by several workers[2–7], but no satisfactory method of artificial excitation has yet been described. We have used a modification of the method originally described by Webster[3] to measure the resonance frequencies of the air column in the trumpet. The apparatus (Fig. 1) operates over the frequency range C_2 (65 Hz) to B_7 (3,951 Hz) (C_4 = middle C) and includes an automatic locking device for the location and tracking of resonance peaks. It gives a digital display and printed record of the amplitude and intonation of each resonance (in cents) relative to the equitempered scale.

It was found that the frequency of each resonance of an instrument corresponded closely with the mean of the frequencies produced for this note by a number of players, so that observations with this apparatus can therefore be used for the basis of quantitative measurement of the intonation of the instrument.

Resonances and tone colour

The resonance frequencies are principally determined by the shape of the bore of the trumpet, and evolution has produced a bore shape with resonances fairly close to the appropriate notes of the equitempered scale. Unfortunately intonation is not the only consideration in fixing the resonances as the following example shows.

Figure 2 shows the first 10 resonances of the tube with their corresponding equitempered frequencies. When the trumpet is

[illegible] COLLEGE

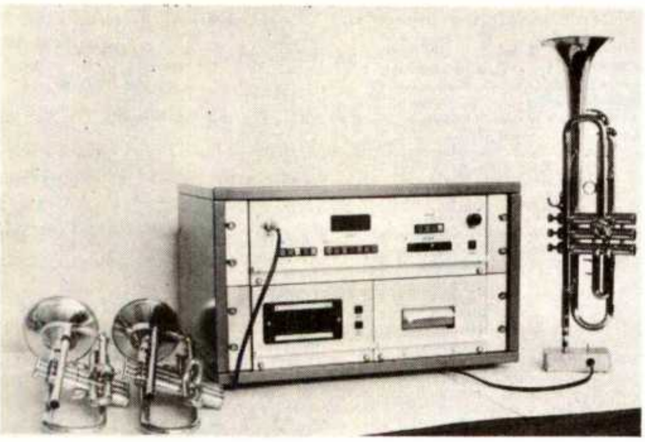

Fig. 1 The apparatus designed to locate automatically and track the resonances of a wind instrument. Digital displays indicate the intonation and amplitude of the resonances.

sounding a steady note, D_5 (587.33 Hz), the frequency of the second harmonic of this fundamental is 1,174.7 Hz, and this strongly excites the resonance at 1,174.7 Hz. This resonance is also near the fourth harmonic (at 1,165.4 Hz) of the fundamental $B\flat_3$ (233.08 Hz). But because this harmonic misses the resonance peak by 14 cents, its strength is not so strongly reinforced, and this has a significant effect on the tone colour of $B\flat_3$.

In practice, the harmonics of any note fall near but not exactly on the resonances of the tube, and are, to varying degrees, reinforced by resonance. The resonances strongly affect the tone colour of notes, and hence the choice of a set of resonances is inevitably a compromise between their intonation when used as fundamentals, and their reinforcement of the harmonics of other notes. We are not concerned here with this compromise, but we show how the design of the bore shape can be modified to move selected resonance frequencies by small amounts to desired values.

Perturbations in the bore

It has been known for many years that small changes in the bore cross section near a node or antinode of the standing wave will change the resonance frequency. A decrease in area at a pressure antinode produces an increase in that frequency, and an increase in area gives a frequency decrease. At a pressure node the effects of changing the area are reversed. We have used perturbation theory to calculate the change in a given bore shape necessary to produce prescribed changes in each of the resonance frequencies.

The pressure oscillations $P_n(x)$, at frequency f_n in a standing wave in the air column in a horn, of cross section $S(x)$, at a distance x from one end, are described by the approximate wave equation[8]

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[S(x)\frac{\mathrm{d}P_n}{\mathrm{d}x}\right]+\frac{4\pi^2 f_n^{\,2}}{c^2}S(x)P_n(x)=0 \tag{1}$$

where c is the velocity of sound. The boundary conditions at the mouthpiece and open end are assumed to be

$$P(x)=\beta\frac{\mathrm{d}P}{\mathrm{d}x}\bigg|_{x=0,L}$$

where the constant β may be different at the two ends of the instrument but the values are assumed to be independent of the mode of oscillation. This is a standard Sturm–Liouville equation and the solutions form a complete orthonormal set[9].

If the cross section $S(x)$ is perturbed by a small change $\delta S(x)$ and $s(x)=\delta S(x)/S(x)$ the first-order change in the resonance frequencies can be shown to be

$$\frac{\delta f_n}{f_n}=\int_0^L s(x)G_n(x)\mathrm{d}x \tag{2}$$

where

$$G_n(x)=\frac{1}{2}S(x)\left\{\frac{c^2}{4\pi^2 f_n^{\,2}}\left[\frac{\mathrm{d}P_n}{\mathrm{d}x}\right]^2-P_n^{\,2}(x)\right\} \tag{3}$$

In deriving this, it is necessary to take δS zero at both ends of the instrument so that the boundary conditions are not changed. The values of $P_n(x)$ used above are taken to be normalised so that

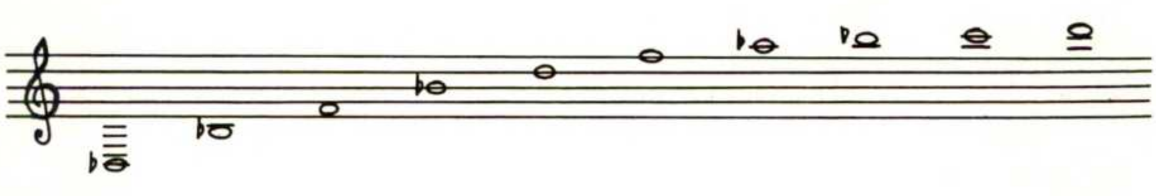
$$\int_0^L S(x)P_n^{\,2}(x)\mathrm{d}x=1 \tag{4}$$

This implies that the dimensions of P are $L^{-3/2}$, and not those of pressure. An alternative expression for $G_n(x)$ can be derived using equation (1)

$$G_n(x)=\frac{c^2}{16\pi^2 f_n^{\,2}}\frac{\mathrm{d}}{\mathrm{d}x}\left[S(x)\frac{\mathrm{d}}{\mathrm{d}x}P_n^{\,2}(x)\right] \tag{5}$$

We wish to prescribe δf_n and calculate $\delta S(x)$. It is clear that the solution is not unique and we shall seek the 'smoothest' change in the bore that produces the required frequency shifts. It may be inconvenient to make changes over the whole instrument, because of the valves and tuning slides, and we shall restrict them to the section $x=0$ to $x=l$. To avoid discontinuities in the bore we need $\delta S(0)=0$ and $\delta S(l)=0$.

Fig. 2 The first 10 resonances of a trumpet with their associated equitempered frequencies. *Not normally used.



Resonance	1*	2	3	4	5	6	7*	8	9	10
Note	$B\flat_2$	$B\flat_3$	F_4	$B\flat_4$	D_5	F_5	$A\flat_5$	$B\flat_5$	C_6	D_6
Frequency (Hz)	116.54	233.08	349.23	466.16	587.33	698.46	830.61	932.33	1,046.5	1,174.7

A suitable measure of smoothness is the mean square derivative

$$\int_0^l S(x)[s'(x)]^2\mathrm{d}x$$

and we minimise this, subject to the constraints that $s(x)$ produces the required frequency shifts using Lagrange's method of undetermined multipliers, that is we minimise

$$\int_0^l S(x)[s'(x)]^2\mathrm{d}x-\sum_{m=1}^{N}\lambda_m\left[\frac{\delta f_m}{f_m}-\int_0^l s(x)G_m(x)\mathrm{d}x\right]$$

The Euler equation for this problem is

$$\frac{\mathrm{d}}{\mathrm{d}x}[S(x)2s'(x)]=\sum_{m=1}^{N}\lambda_m G_m(x)$$

$$=\frac{c^2}{16\pi^2 f_m^2}\sum_{m=1}^{N}\lambda_m\frac{\mathrm{d}}{\mathrm{d}x}\left[S(x)\frac{\mathrm{d}}{\mathrm{d}x}P_m^2(x)\right]$$

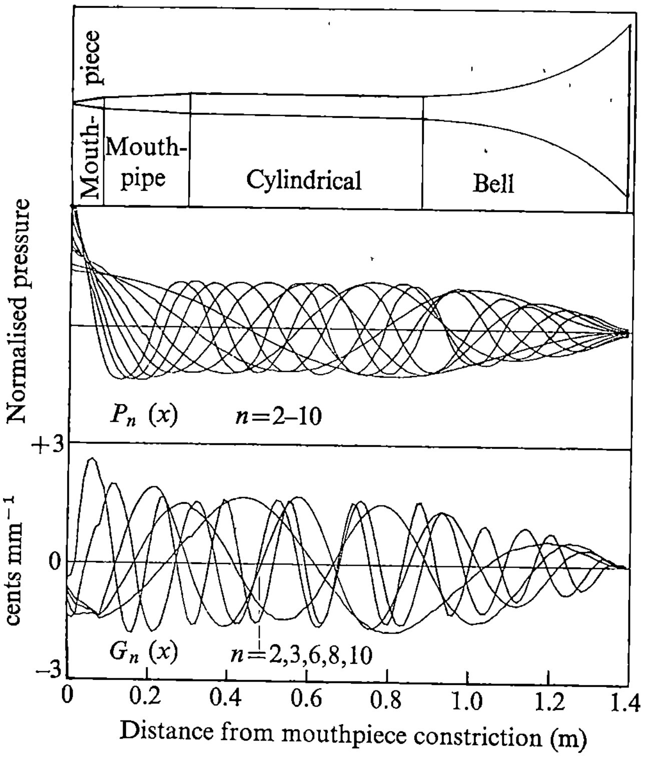
Integrating twice gives

$$s(x)=\sum_{m=1}^{N}\mu_m P_m^2(x)+A\int_0^x\frac{\mathrm{d}\xi}{S(\xi)}+B \qquad (6)$$

A and B are arbitrary constants of integration and they can be chosen to make $\delta S(0)=0$ and $\delta S(l)=0$, and μ_m is a multiple of λ_m.

Substituting this into (2) gives N linear equations which, together with the conditions on δS, determine the $N+2$ constants μ_m, A, B. Equation (6) then gives the required change in bore.

Fig. 3 The physical shape of a trumpet (not to scale) with $P_n(x)$ and $G_n(x)$ for selected modes.



The reader may wonder why we have used the 'smoothest' perturbation rather than the 'smallest' one. If we define

$$\varepsilon=\int_0^l[s(x)]^2\mathrm{d}x$$

and find the function $s(x)$ that minimises this and produces the required frequency shifts we get

$$s(x)=\sum_m\mu_m G_m(x) \qquad (7)$$

This cannot, however, be used as a solution to our problem as it does not ensure that $\delta S(0)=0$ and $\delta S(l)=0$.

The eigenfunctions for the standing waves

To perform the calculations of the previous section the functions $P_n(x)$ are required. Although it is possible, in principle, to calculate these given the cross-sectional area of the trumpet, it is undoubtedly easier to observe them.

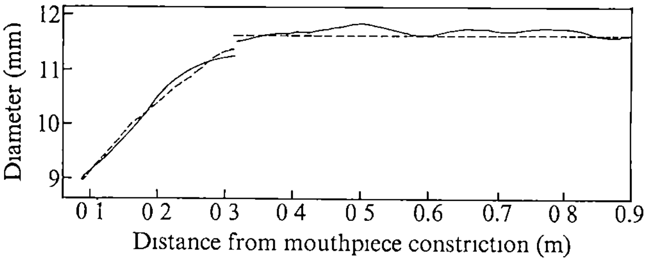


Fig. 4 The bore shape of a trumpet (conical and cylindrical portions) before and after perturbation. ——, Perturbed bore; — —, original bore.

In a standing wave, when damping is very small, the oscillations have the same phase at all points between adjacent nodes, and the phase changes by π across each node. The result is not exact if damping is included, but as we have neglected damping, even in equation (1), there is no advantage in observing the phase of the pressure oscillations, and we assume the phase is 0 or π. The function $P_n(x)$ is therefore given by the observed pressure amplitude between alternate pairs of nodes and minus the observed pressure in the gaps.

The derivative $\mathrm{d}P_n/\mathrm{d}x$ is also required. Because of the well known dangers of numerical differentiation we obtain this by integrating equation (1) giving

$$\frac{\mathrm{d}P_n(x)}{\mathrm{d}x}=-\frac{4\pi^2 f_n^2}{c^2 S(x)}\int_0^x S(\xi)P_n(\xi)\mathrm{d}\xi+\frac{C}{S(x)}$$

The value of the constant of integration C is found by integrating again, thus introducing another constant, and finding both constants by satisfying the equations at two particular values of x.

Varying the length of pipe over which the perturbation is made

An interesting result can be derived about the mean square perturbation, which can be evaluated using equation (7). This can be differentiated with respect to l, bearing in mind that the numbers μ depend on l. The derivatives of μ can be eliminated by differentiating equation (2) and we get the remarkable result

$$\frac{\partial\varepsilon}{\partial l}=-[s(l)]^2 \qquad (8)$$

It follows that $\partial\varepsilon/\partial l$ is never positive, and the mean square value of the perturbation required always decreases as we spread the perturbation over longer lengths of the tube.

Asymptotic results

The high eigenvalues of a Sturm–Liouville equation have simple asymptotic distributions[9]. When n is large, $f_n \sim nc/2L$ and

$$P_n(x) \sim \left(\frac{2}{LS(x)}\right)^{1/2} \cos\left[\left(n-\frac{1}{2}\right)\frac{\pi x}{L}+\theta_n\right]$$

in which θ_n depends on the boundary conditions. A musical instrument like the trumpet has evolved into a shape such that the frequencies of the resonances are almost uniformly spaced. In other words, the formula $f_n \sim nc/2L$, which can be proved for large n, is in fact almost exact for all n. This suggests that the associated asymptotic eigenfunctions, $P_n(x)$, might be good approximations for all n. This would avoid the difficult measurement of $P_n(x)$. If the boundary conditions in the trumpet are approximately

$$P_n(L) = 0 \text{ and} \left[\frac{\mathrm{d}P_n}{\mathrm{d}x}\right]\Bigg|_{x=0} = 0$$

we can show that

$$G_n(x) \sim -\frac{1}{L}\cos\left(\frac{(2n-1)\pi x}{L}\right)$$

The integrals involved in the calculations can now be evaluated analytically.

We have tested the usefulness of this by prescribing some values for δf_n, calculating the bore shape required using the asymptotic expression for $G_n(x)$ and then calculating the exact frequency shifts (equation 2) that this bore shape would produce, using the correct observed value of $G_n(x)$. The changes produced are found to be in the right direction, but the magnitude of error is large. The asymptotic results can, however, be usefully employed if (a) a rapid approximate answer is required: the measurement of $P_n(x)$ is time consuming, or (b) if a very high harmonic needs adjustment, where the observations of the resonance are impossible.

Verification of the theory

The trumpet was driven by the automatic tuner described in the first section and the sound pressure was measured in two ways; using probe tubes inserted radially through holes in the bore at each centimetre of the instrument's length and using a long flexible probe drawn through the instrument. There was little variation between the results of either method and they are shown with the computed functions $G_n(x)$ in Fig. 3.

An earlier section has indicated the difficulties involved in deciding upon the optimum intonation of an instrument. To verify our ideas, however, these arbitrary changes were chosen: for the fifth and tenth order resonance, a change of +5 cents for the sixth order resonance a change of −5 cents, and all other resonances to be unaltered. Similarly, the perturbed length was arbitrarily restricted to the first 0.9 m of the instrument. This bore provides the 'open' notes of the instrument and additional tubing is inserted by valves to produce a chromatic scale. Consequently the effect of our perturbation is likely to be less accurate as more tubing is added; the perturbation method could be applied to this valve tubing for further correction to notes using valve tubes. Equation (8) implies that because of the relatively short length of the valve tubing, only small intonation corrections could be made in this way without unacceptably large diameter changes.

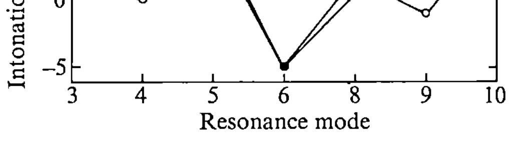

Fig. 5 Relative intonation of seven resonance modes. ●, Required change in intonation; ○, change obtained by perturbation.

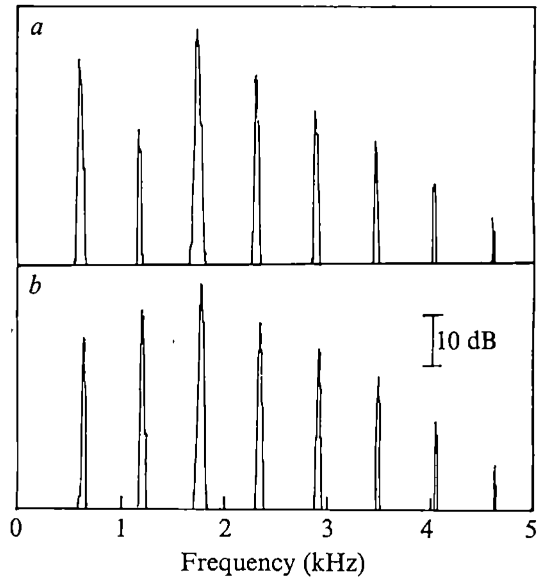

Fig. 6 The spectra of note D_5 (587.33 Hz) blown by a professional musician. (*a*) before, and (*b*) after perturbation. Both notes were played *mezzo forte* in an anechoic chamber with the michrophone at 1 m along the axis of the instrument.

A graph of the new bore shape (Fig. 4) indicates a maximum change in diameter of < 0.2 mm. This may be compared with a maximum of 0.14 mm for the smallest mean square perturbation mentioned earlier.

The new shape was reproduced with glass reinforced plastic and its resonances measured using the automatic tuner. There is close correspondence between the required and measured intonation (Fig. 5); the small errors mainly arise from the difficulty in producing a new bore to an accuracy of better than 0.02 mm.

It can be appreciated from the qualitative effects of diameter changes at nodes and antinodes that some prescribed frequency shifts may require conflicting diameter changes. The result in these cases is that very large increases and decreases in diameter are required over short distances. These would be unacceptable for a musical instrument and would also render our first-order perturbation theory invalid. Our optimisation procedure makes sure that large changes in diameter are not used unnecessarily.

For comparison another calculation has been made which assumes a non-optimum bore shape given by a superposition of sine waves. The maximum diameter change required here was 3 mm.

Curing a faulty trumpet

Although the foregoing theory is not ideally suited to the complete acoustical design of a new instrument, the best application of this work is with the improvement of the individual notes of prototype or production instruments. One such instrument was found to have a weak second harmonic when playing D_5 (587.33 Hz) (Fig. 6*a*). As already mentioned, this harmonic uses the tenth resonance for reinforcement; and this was found to be flat with respect to the fifth. The tenth resonance is not normally played as a fundamental and hence can be altered to improve the tone colour. Using our new technique we were able to raise this tenth resonance by ten cents to give the improved response (Fig. 6*b*).

This work was supported in part by the SRC and Boosey & Hawkes Ltd. We thank Dr D. M. A. Mercer for encouragement and also acknowledge the assistance of Mr W. Tompkins and the trumpet player, Michael Laird.

letters to nature

Does Mercury have a molten core?

THE discovery of an intrinsic magnetic field for the planet Mercury by Mariner 10 (ref. 1) and its preferred source in an internal dynamo[2] imply the existence of a conducting molten core. We propose here a feasible, non-seismic observational experiment to determine the existence and extent of such a molten core, which would be vital for calculations of Mercurian thermal histories and dynamo field generation.

Siegfried and Solomon[3] have calculated two thermal histories for Mercury leading to a differentiated and an undifferentiated planet respectively. In the latter models, of course, Mercury would have no core. Even in the differentiated model a once molten core tends to solidify as the planet cools. Whether or not a given differentiated model leads to a molten core persisting to the present depends critically on assumptions about initial conditions (the time of core formation), the time varying distribution of radioactive elements within the planet, thermal conductivities and the extent and efficiency of convective heat transport. Even with all the radioactive elements being removed from an initially differentiated molten core, Fricker *et al.*[4] have shown that a liquid outer core 500-km thick may still persist if one accounts for a thermal barrier at a liquid iron–solid silicate core–mantle boundary. The thermal barrier results from the higher melting point and lower thermal conductivity of the silicates—the liquid iron core temperature rises above the melting curve near the core–mantle boundary thereby decreasing the core temperature gradient. If the solid mantle is allowed to convect, however, it must contain a density of heat sources comparable to the Earth's mantle-wide average if the core is to remain molten[5].

Since we cannot be certain about the convective heat transport or the distribution of heat sources, theoretical predictions about the nature of the Mercurian core are not conclusive. There is thus a severe need for the experimental determination of some of the key internal parameters or, more directly, for an experiment which would determine unambiguously the extent of any fluid core. The latter would motivate considerable research into the generation of planetary magnetic fields and would place bounds on the internal parameters related to the thermal history—whether or not the core was found to be molten. Fortunately, the effects of a liquid core on the dynamics of Mercury's rotation affords a technically feasible, albeit expensive means of determining unambiguously the nature of Mercury's core[6].

There are two necessary conditions for this scheme to work. First, a liquid core must not follow the mantle's forced librations (88-d period) in longitude, which arise from the periodic solar torque on its asymmetric mass. Second, the core must follow the mantle on the time scale of the 250,000-yr precession. We shall assume these two conditions are satisfied to develop the method and subsequently establish bounds on the core viscosity for which they are satisfied.

The amplitude of the physical librations in longitude with the period of a Mercury year is[7]

$$\varphi_0 = \frac{3}{2}\left(\frac{B-A}{C_m}\right)\left(1-11e^2+\frac{959}{48}e^4+\ldots\right)\simeq\frac{B-A}{C_m} \qquad (1)$$

where $A<B<C$ are principal moments of inertia of the entire planet, e is the orbital eccentricity and C_m is the moment of inertia of the mantle alone. The physical libration is thus larger than it would have been if the core were solid. (The core is assumed axially symmetric, so it does not contribute to $B-A$.) The tides carry Mercury to a configuration which is a generalisation of Cassini's laws for the Moon[8], where the spin axis, orbit normal and normal to the invariable plane remain coplanar as the first two vectors precess around the last with a 250,000-yr period. In this 'Cassini state', the following relation is satisfied[8,9]

$$K_1(\theta)\left(\frac{C-A}{C}\right)+K_2(\theta)\left(\frac{B-A}{C}\right) = K_3(\theta) \qquad (2)$$

where K_1, K_2, K_3 are constants involving the orbital eccentricity, inclination and mean motion and the planetary spin angular velocity and explicitly the obliquity θ. In equation (2), $K_2 \ll K_1$ and can sometimes be neglected as it has been in the classical determination of $(C-A)/C$ for the Moon[9]. Note that C and not C_m is appropriate here, because of our assumption that any liquid core is able to keep up with the mantle precession. Also, θ and φ_0 are measurable quantities.

The second degree gravitational harmonics are related to the moment of inertia differences by

$$J_2 = \frac{C-A}{MR^2} - \frac{1}{2}\frac{(B-A)}{MR^2} \qquad (3)$$

$$C_{22} = \frac{B-A}{4MR_2}$$

where M and R are the planetary mass and radius respectively. Equations (3) can be solved for $(B-A)/MR^2$ and $(C-A)/MR^2$ in terms of J_2 and C_{22}, where the latter two quantities can be determined by tracking one or more artificial satellites. Substitution of the solutions of equations (3) into equation (2) yields a numerical value for C/MR^2 since the K are known once the obliquity θ is determined. This number, already determined for the Moon by the same procedure[10], is a measure of the density distribution in the planet. ($C/MR^2 \simeq 0.33$ for the Earth, $\simeq 0.40$ for the Moon, $\simeq 0.40$ for an homogeneous sphere.)

Finally, measurement of the amplitude of the physical libration φ_0 yields $(B-A)/C_m$ from which three known factors yield

$$\left(\frac{C_m}{B-A}\right)\left(\frac{B-A}{MR^2}\right)\left(\frac{MR^2}{C}\right) = \frac{C_m}{C} \leq 1 \quad (4)$$

A value for C_m/C of 1 would indicate the core to be firmly coupled to the mantle and hence most probably solid. If the entire core or the outer part is fluid, $C_m/C \simeq 0.5$ for the large core size ($R_c \simeq 0.75R$) in current models of the interior[5].

How good are the assumptions that a fluid core will not follow the short period physical librations but will follow the long period precession? The appropriate time scale to compare with the 88-d and 250,000-yr periods is the 'spin up' or 'spin down' time for the core fluid (rotating at a slightly different angular velocity) to approach the perturbed angular velocity of the mantle[11].

$$\tau = R_c/(\nu\dot{\psi})^{\frac{1}{2}} \quad (5)$$

where R_c is the core radius, ν is the kinematic viscosity and $\dot{\psi}$ is the spin angular velocity of the planet. If $\tau > 88$ d the core will not follow the mantle libration, whereas if $\tau < 250{,}000$ yr, the core will follow the mantle precession. These bounds on τ lead to the bounds on ν of

$$8\times10^{-4} < \nu < 2\times10^{9}\ \mathrm{cm^2\ s^{-1}} \quad (6)$$

where both necessary conditions for the determination of C_m/C are satisfied if ν is within these bounds. This is almost certainly true since the range in equation (6) includes the complete range estimated for the Earth's core of 5×10^{-3}–10^7 cm² s⁻¹ (ref. 12).

The numbers φ_0, θ, J_2 and C_{22} must be determined to find C_m/C and hence the extent of the Mercurian liquid core. The first two are O(20″–40″) and O($\lesssim 1°$) (ref. 9, and B. A. Smith, personal communication) respectively and will almost certainly require rather sophisticated instrumentation on the surface of the planet. The latter two can be obtained from precise tracking of artificial satellites. The design of instrumentation to measure the small angles φ and θ which is within the weight limitations and which will survive the possibly hard landing of any spacecraft sent to Mercury's surface is a severe challenge. The large scientific return which could, however, be realised from such surface instrumentation means that the attempt at the design should be made.

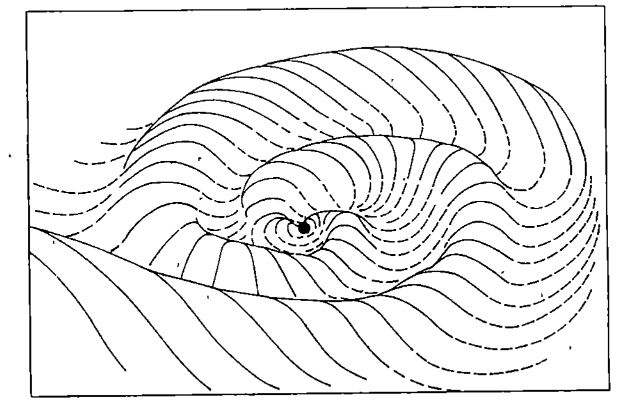
Structure of the extended solar magnetic field and the sunspot cycle variation in cosmic ray intensity

THE interplanetary magnetic field within several astronomical units of the Sun appears to have one polarity in most of the hemisphere north of the solar equatorial plane and the opposite polarity in most of the hemisphere south of the equatorial plane[1–7]. The two hemispheres are separated by a curved current sheet that typically crosses the solar equatorial plane in either two or four places, thus dividing the equatorial region into either two or four sectors. Near sunspot minimum, at 1 AU the curved current sheet has a spread in latitude of typically ± 15°, so that the sector boundary (the current sheet separating the two hemispheres of opposed field polarity) is almost parallel to the solar equatorial plane. In the photosphere, on the other hand, the sector boundary makes an angle of ~ 90° with the equatorial plane[8]. At $1.5R_\odot$, in 1972 and 1973, the angle between the sector boundary and the equatorial plane was ~ 45° (ref. 9), and at 3–$10R_\odot$ the angle between boundary and plane was ~25° (ref. 10). A schematic diagram of this structure for the case of four sectors is shown in Fig. 1. We here propose that a connection exists between the extent of these magnetic fields and the observed variations in cosmic ray intensity at the Earth.

In the photosphere, near sunspot minimum, the sector magnetic fields cover a range in latitude of typically ±40° (ref. 8), while at 1 AU the comparable range in latitude has been compressed to perhaps ±15°. How is this compression in latitude accomplished? A typical magnitude of the sector magnetic fields in the photosphere is 0.5 gauss (P. H. Scherrer and T. L. Duvall, personal communication). This is a measure of the large scale field that will dominate in the region a few $R_\odot$ above the photosphere, where the smaller scale but much stronger fields associated with active regions do not reach. In the polar regions of the Sun the large scale unidirected photospheric field has a typical magnitude of perhaps 5 gauss (R. Howard, personal communication). Thus, at 1 or $2R_\odot$

Fig. 1 Schematic showing the warped current sheet in the inner Solar System (inside 6 AU). This current sheet divides the interplanetary magnetic field in the heliosphere into two regions with oppositely directed field lines. In one region the field polarity is away from the Sun (at present this region is north of the solar equator), in the other region the field polarity is toward the Sun. The situation is shown for a four-sector structure, that is, as the current sheet is rotated past a stationary observer in the course of a solar rotation, the observer will see four changes of magnetic polarity, suggesting that the interplanetary magnetic field is divided into four sectors of alternating polarity. Where the current sheet lies above the solar equatorial plane it is shown by full lines, while dashed lines indicate that the current sheet is below the equatorial plane. The extent in latitude of the current sheet was assumed to be ±15°. The Sun at the centre is not shown to scale.



above the photosphere, and above the region of influence of active regions, the magnetic pressure associated with the solar polar regions is two orders of magnitude larger than the magnetic pressure associated with the equatorial sector structure. This will compress the equatorial sector field structure into a narrow range of latitudes. This effect can be clearly seen in the sketch in Fig. 2 made from an eclipse photograph taken at solar minimum in 1954 (ref. 11).

During an interval near sunspot maximum, when the solar polar field polarities are reversing, the magnitude of the polar fields may be considerably less, and the resulting compression of the equatorial field structure also much less. The sector structure fields may then occupy a much larger fraction of the heliosphere. Since the sector structure fields reverse polarity typically four times or two times per solar rotation, a galactic cosmic ray headed towards the Sun may encounter considerably more magnetic scattering from the complex sector structure field than from the unidirectional field that fills most of each solar hemisphere near sunspot minimum. This geometrical effect may be the principal cause of the 11-yr modulation of cosmic-ray intensity observed at the Earth, since the solar-wind velocity[12] and the magnitude of the interplanetary field[13] observed near the Earth have not changed very much during the present sunspot cycle.

The fraction of the heliosphere occupied by sector-structure fields as a function of time through an average sunspot cycle can be estimated in the following way. Because the current sheet shown in Fig. 1 is warped with respect to the solar equatorial plane, during the half year when the earth is north of the equatorial plane an interplanetary sector with the same polarity as the northern solar polar region is observed to be wider than it would be if observed when the Earth is in the equatorial plane of the Sun. For example, assume that there are two sectors per solar rotation and that the extent in heliographic latitude of the sector structure near the Earth is ±20°. When the Earth is at a latitude near 7°N (near September 7), the sector whose polarity is the same as the northern polar region will be observed to last 16.5 d, as compared with the 13.5 d it would last if observed when the Earth is near the solar equatorial plane. For comparison, if the extent in heliographic latitude of the sector structure near the Earth is ±45°, then the sector with the same polarity as the northern polar region will have a length of 14.6 d when observed near the Earth at 7°N. We see that if we measure the magnitude of this Rosenberg–Coleman effect[14,15] through a sunspot cycle we can estimate the extent in heliographic latitude of the sector structure.

We have used an harmonic analysis to compute the average amplitude of the Rosenberg–Coleman effect as a function of years from the time of sunspot minimum for the four sunspot cycles whose minima were near 1934, 1944, 1954 and 1965. Interplanetary field polarities inferred from polar geomagnetic variations[16] were used, and the resulting amplitude of the Rosenberg–Coleman effect was multiplied by 1.43 to correct for the ~85% accuracy[17,18] of the inferred interplanetary field polarities.

Figure 3 shows the resulting value for the extent in heliographic latitude of the sector structure through an average sunspot cycle. Three-year running means were used to reduce the scatter. Year 0 is the average of the sunspot minimum years 1934, 1944, 1954 and 1965. The effect of uncertainties in the computation of the magnitude of the Rosenberg–Coleman effect will usually be to decrease the amplitude of the effect and, therefore, the latitude values shown in Fig. 3 should be considered upper limits. We may expect considerable variation from the average effect shown in Fig. 3, and in particular for intervals of several months near sunspot minimum the current sheet may occupy only a few degrees of latitude.

As a first approximation, we assume that galactic cosmic rays have relatively difficult access to the inner Solar System in the portion of the heliosphere occupied by the changing fields of the sector structure, and relatively easy access through the portions of the heliosphere occupied by the extended uniform solar polar fields. This assumption is consistent with the observational evidence now available. A final evaluation must await *in situ* observations with out-of-ecliptic spacecraft. It is also observed[8] that high speed solar wind streams are contained within sectors. Kinks and irregularities in the interplanetary magnetic field that can scatter cosmic rays are produced as the fast plasma in a high speed stream overtakes slower plasma. The solar-wind plasma coming from higher solar latitudes may have a more uniform (albeit larger) velocity than the solar wind plasma from lower solar latitudes, and thus be not as effective in producing scattering of cosmic rays.

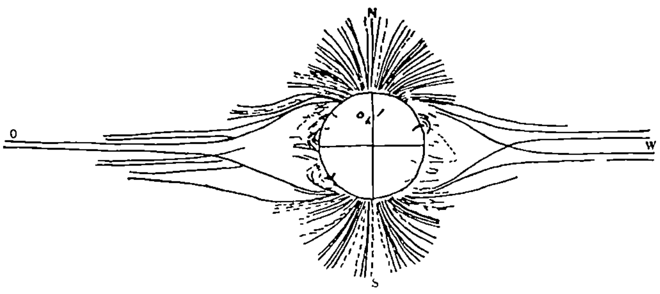


Fig. 2 The structure of a sunspot minimum solar corona drawn from eclipse photographs[11] (June 30, 1954) obtained in Kozeletsk.

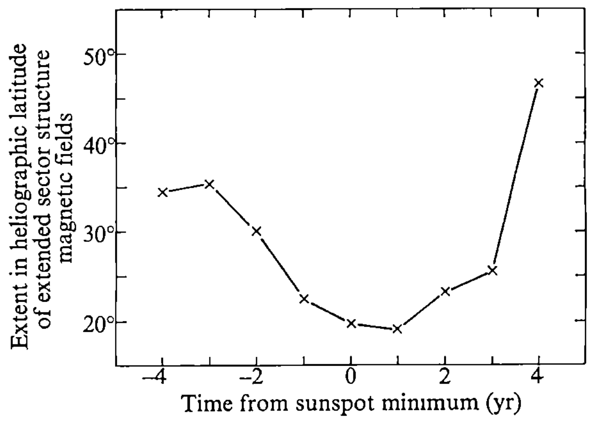
In Fig. 4 we show the solid angle of the heliosphere occupied by the extended solar polar fields through an average sunspot cycle, where the latitude angles shown in Fig. 3 are used to compute the solid angles shown in Fig. 4. Also shown in Fig. 4 are the monthly averages of the absolute intensity of primary cosmic rays of rigidity > 0.5 GV observed near Murmansk and at Mirny from 1958 to 1973 (ref. 19). The total flux of such galactic cosmic rays in the interstellar medium in the vicinity of the earth is estimated to be 4,000 $m^{-2} s^{-1} sr^{-1}$ (ref. 19). Therefore, in Fig. 4 we have set the total solid angle 4π of the heliosphere as equivalent to a flux of 4,000 $m^{-2} s^{-1} sr^{-1}$, and the zero of the solid angle scale corresponds to zero flux. This corresponds to the assumption that galactic cosmic rays have easy access to the inner Solar System through the solid angle of the heliosphere occupied by the extended solar polar fields, and difficult access through the solid angle occupied by the sector structure fields.

In Fig. 4 we see that the average sunspot cycle variation of the solid angle of the extended solar polar fields is rather similar to the observed variation of the flux of primary cosmic rays of rigidity > 0.5 GV between 1961 and 1969. We should not

Fig. 3 Computed variation of the average extent in heliographic latitude of the extended solar sector magnetic fields. Year 0 is the average of the sunspot minimum years 1934, 1944, 1954 and 1965. The value 20° on the ordinate means that the extended sector fields are in the interval 20°N to 20°S.



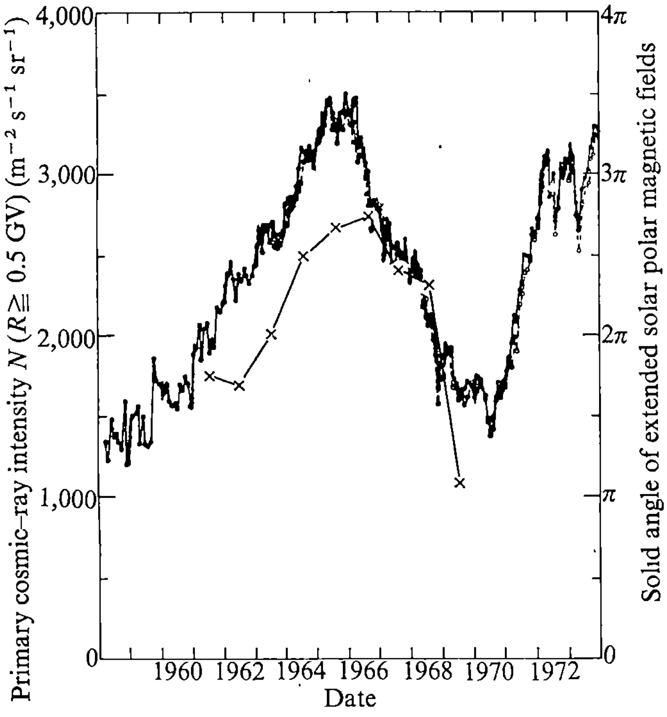


Fig. 4 Galactic cosmic-ray intensities with rigidity 0.5 GV observed near Murmask (●) and at Mirny (○) from 1958 to 1973 (ref. 19). Also shown is the computed average solid angle (×) of the heliosphere occupied by the extended solar polar magnetic fields.

expect a detailed agreement between the computed variation of solid angle averaged over four sunspot cycles and the observed cosmic-ray flux around a single sunspot minimum. The similarity of the two curves in Fig. 4 suggests that there may be some validity to the considerations advanced in this paper. The detailed computation of the diffusion lengths of cosmic rays related to these considerations is beyond the scope of this paper.

Glass-rich basaltic sand and gravel within the oceanic crust at 22°N

During Leg 46 of the Deep Sea Drilling Project (January 29–March 10, 1976), the second leg of the International Phase of Oceanic Drilling, the Glomar Challenger drilled into 255 m of basaltic basement at hole 396B, 160-km east of the Mid-Atlantic Ridge valley at 22°59.14′N, 43°30.90′W. The hole was drilled into crust with a magnetic anomaly age of ~ 10 Myr. This site is located in a N–S trending sediment pond which measures ~ 4 km × 10 km and is concordant with local topographic trends. There are 150 m of sediment at the drill site; however, the basement slopes regionally to the east and sediment thickness is probably > 250 m along the fault-bounded (?) eastern margin (G. M. Purdy, unpublished, and report of work by the Soviet research vessel Akademik Kurchatov). The bottom 90 m of this hole contained basaltic sand and gravel. This material is not believed to be a drilling artefact, but caused by *in situ* spalling or brecciation of basaltic pillow rinds.

On a number of other occasions, for example, on Legs 34 and 45, there was some indication, principally the sticking or jamming of the drill bit within young basement, that clastic zones had been encountered. At hole 396B a zone of rapid penetration was followed by an interval of difficult drilling and frequent sticking of the bit which eventually led to termination of drilling. In the lower part of the hole, the core catcher assembly was modified to catch fine clastic material and in cores 30 and 33, the core barrel contained 82 and 90 cm respectively, of basaltic gravel and sand. The recovery rate immediately above these two intervals was < 1% and on the basis of this and other shipboard data, in particular results from a unique downhole logging programme, we believe that the clastic zone was first encountered at 310 m sub-bottom and was apparently continuous down to at least 405.5 m where the hole was abandoned.

Stratigraphic units within 396B were determined on the basis of macroscopic and microscopic lithologies, magnetic properties, chemical composition, alteration features and density of recovered samples. In addition, we have been able to correlate these units with downhole logging records which include sonic velocity, natural γ-ray intensity, porosity, density and electrical conductivity. Figure 1 summarises the general lithologies, magnetic inclination, chemical stratigraphy (typified by TiO_2 concentrations) and dual induction lateral (conductivity) log. All indicators show a marked change in character below the 310-m depth where samples of the clastic material were first recovered.

The gravel and sand from cores 30 and 33 are largely in the coarse sand to fine gravel size range (0.5–3.0 mm) and are moderately sorted. The sorting, however, may be the result of preferential loss of fine grained material during core recovery. The fragments are generally non-vesicular and consist of angular chips of glass and variolitic, cryptocrystalline and intersertal basalt. Olivine and plagioclase occur as phenocrysts in the clasts and as crystal fragments. A small number of pieces of calcite-cemented basaltic microbreccia, a few chips with calcite spherules and clasts with cross-cutting calcite veins were found. In general, the glass appears quite fresh, palagonite rims are uncommon and few palagonite fragments were found.

Two small fragments (5–10 cm) of bedded hyaloclastite were also recovered in core 30. One of these samples is a moderately indurated fine to coarse grained hyaloclastite sandstone with graded bedding and evidence for scouring. Both rocks offer clear evidence for some sort of current action and the redistribution of dominantly sand-sized fragments of sideromelane and fine grained basalt.

The last 90 m, which we have called the clastic zone, is divided into four units: an upper clastic breccia, an upper basaltic gravel, a plagioclase phyric pillow basalt (breccia ?) and a lower gravel unit. The two gravel units seem to have been derived locally. Crystalline fragments in the upper gravel are

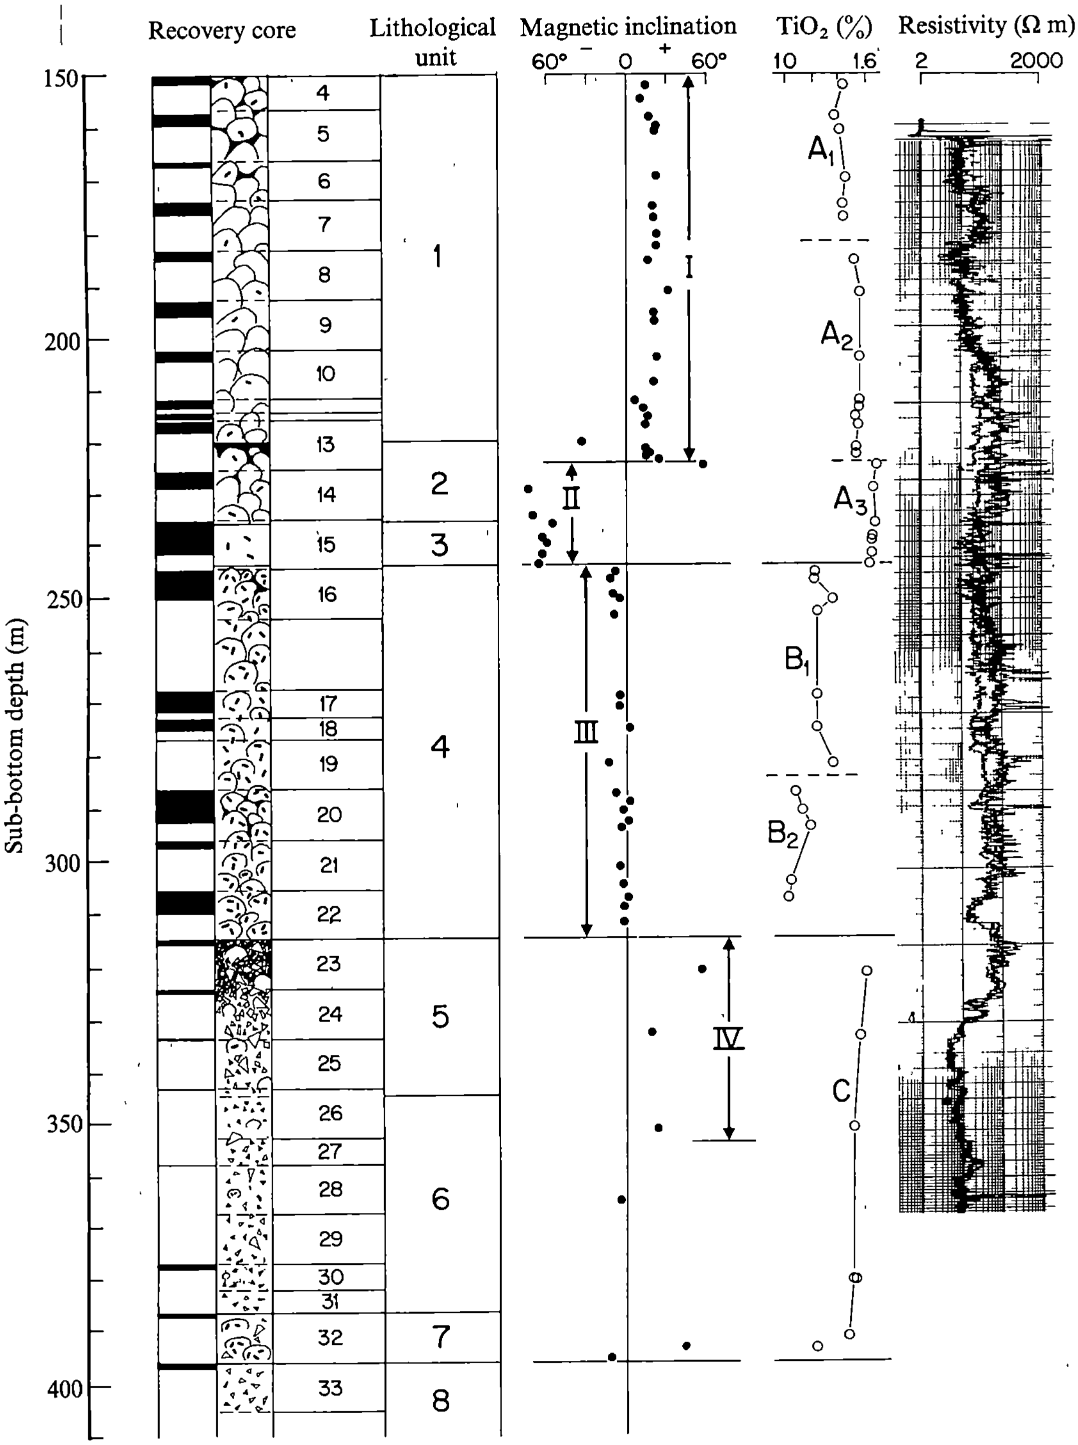

Fig. 1 Variations of lithological units, magnetic inclination, TiO_2, and electrical resistivity log as a function of depth below the sea floor for hole 396B.

dominantly olivine–plagioclase phyric with proportions of olivine to plagioclase (ol.–plag. = 0.55) similar to the basalt in the overlying breccia unit, but unlike the basalt cored previously above the clastic zone. The lower gravel unit, on the other hand, contains predominantly plagioclase phyric crystalline fragments (ol.–plag. = 0.13) similar to the intervening plagioclase phyric pillow basalt (breccia?).

Four major processes may be invoked to explain the fragmentation of the basalt:

(1) Fragmentation during eruption and cooling: this may involve several interrelated processes peculiar to submarine lava flows. (a) Glassy fragments could form by granulation due to thermal shock resulting from quenching of lava by seawater. (b) Spalling and crumbling of pillow rinds as a result of continued or multiple flow of basaltic lava causing inflation of a pre-existing pillow crust. (c) Brecciation from the oversteepening of pillow mounds causing them to tumble or slump. Mechanical shock from earthquakes or other tectonic processes may facilitate in this type of break-up.

(2) Tectonic brecciation after consolidation. Faulting and fissuring within the median valley, and on the flanks and away from the ridge is ubiquitous.

(3) Erosion, transport and deposition including the formation of talus slopes associated with fault scarps. Erosion would probably be largely restricted to reworking of material previously broken by processes 1 and 2.

(4) Shaving or reaming out of the hole by the drill bit during re-entry or fragmentation by drilling.

Origin 4 is unlikely: no re-entry was made immediately before coring the fragmented debris; the penetration rates were exceptionally high; lithified sandstone fragments were found with the loose gravel and sand; the lithic clasts do not seem to have been derived from higher in the bore hole and the data from the downhole logs strongly suggests that the clastic material represents a distinct lithological unit. The abundance of fragments of basaltic glass in the clastic material indicates that much or all of it is derived from basaltic pillows; however, as the majority of the fragments are partly crystallised (origin 1(a)), spallation of glass rinds on quenching, would seem to be ruled out as a major source for the clastic material. The calcite fragments, spherulites, clasts with cross-cutting calcite veins and calcite cemented basaltic microbreccia fragments demonstrate that some of the gravel and sand must be late clastic debris from previously altered flows. On the basis of available data, however, it is impossible to make a clear choice between origins 1(b), 1(c), 2 and 3 as the predominant source of the gravel sand and other clastic debris in the clastic zone.

Although deposits of coarse talus have been well known for many years from photographs of the sea floor we believe that this is the first time that a deposit of relatively fine grained clastic material has been recovered from beneath the sea floor, and it represents a hitherto unknown element among these rocks. We have provided evidence that it comprises the greater part of the lower 90 m of the core, but may extend deeper. Since this material cannot be strongly magnetised and cannot contribute to the lineated magnetic anomalies of this region, it probably does not make up a significant portion of the basement.

We wish to thank Captain Lloyd E. Dill and his ship's crew, Cotton Guess, Drilling Superintendent, and his drilling crew, Robert Knapp, Operations Manager, G. Bode and the DSDP technicians and Dalhousie University, CNEXO, Schlumberger Well Services for supplying major equipment and services. The post-spinel phase of forsterite

THE nature of the post-spinel phase of forsterite (the olivine structure of Mg_2SiO_4) and its importance to our understanding of the mineralogy, petrology and seismological discontinuities in the transition zone and the lower mantle of the Earth has attracted much recent attention[1,2]. Kumazawa *et al.*[1] reported that the post-spinel phase of forsterite recovered from 3.3×10^{10} Pa and 1,000 °C was a component oxide mixture of stishovite (SiO_2) plus periclase (MgO). In their studies of Mg_2SiO_4–Fe_2SiO_4 solid solutions at pressures up to 2.5×10^{10} Pa, Ming and Bassett[2] agreed with the conclusions of Kumazawa *et al.* Consequently, the oxide mixture seems to be widely accepted as the post-spinel phase of forsterite[3]. In this paper, however, I present results that disagree with this.

I have previously found that forsterite transforms into an assemblage of perovskite ($MgSiO_2$) plus periclase (MgO) when subjected to pressures $> 3.0\times 10^{10}$ Pa and $\sim$ 1,000 °C (ref. 4). Since the zero pressure density for the perovskite + periclase assemblage is 1.9% greater than that of the mixed oxides, I have designated this assemblage as the post-oxide phase of forsterite and have postulated that the Earth's lower mantle comprises mainly the perovskite phase of $MgSiO_3$ (ref. 5).

Until my work on the detailed high pressure phase transformations in $MgSiO_3$ (ref. 6), I had not doubted the interpretation of the post-spinel phase for Mg_2SiO_4 as representing mixed oxides. A schematic isothermal phase diagram for the system MgO–SiO_2 at 1,000 °C is shown in Fig. 1. If Mg_2SiO_4 were to disproportionate into its component oxide mixture at certain pressure and temperature conditions, so also should $MgSiO_3$. The latter, in fact, has been reported by Ming and Bassett[7] who have found that $MgSiO_3$ disproportionates into its component oxides, stishovite plus periclase, at a pressure of $\sim 2.5\times 10^{10}$ Pa. In my recent study of the high pressure phases of $MgSiO_3$ between 1.5×10^{10}–3.0×10^{10} Pa loading pressure[6], however, I have found that the sequence of phase transformations in $MgSiO_3$ with increasing pressure is as follows

$$\begin{array}{ccccccccc} 2MgSiO_3 & \rightarrow & Mg_2SiO_4 & + & SiO_2 & \rightarrow & Mg_2SiO_4 & + & SiO_2 \\ \text{clinoenstatite} & & \beta\text{ phase} & & \text{stishovite} & & \text{spinel} & & \text{stishovite} \end{array}$$

$$\begin{array}{cccc} \rightarrow & 2MgSiO_3 & \rightarrow & 2MgSiO_3 \\ & \text{ilmenite} & & \text{perovskite} \end{array}$$

If there were a stability field for the mixed oxides, it would have intervened between the ilmenite and the perovskite phases.

The ilmenite phase of $MgSiO_3$ transforms directly into the perovskite phase with increasing pressure. This behaviour is consistent with phase transformations observed in all the available ilmenite analogues, $CdTiO_3$ (ref. 8), $CdSnO_3$ (ref. 8), $MnVO_3$ (ref. 9), (Fe,Mg)TiO_3 (ref. 10), $MnGeO_3$ (ref. 11), and $MgGeO_3$ (L.L., unpublished). With the exception of $ZnSiO_3$, for which only a very small stability field of mixed oxides has been reported[12], the ilmenite phase of all the above-mentioned compounds has been found to transform directly into the

perovskite phase without the intervention of any other phases.

The fact that the ilmenite phase of $MgSiO_3$ transforms directly into the perovskite phase limits the post-spinel phase for Mg_2SiO_4 to the following possibilities: (1) a single denser phase of Mg_2SiO_4; (2) a mixture of ilmenite ($MgSiO_3$) plus periclase (MgO); (3) a mixture of perovskite ($MgSiO_3$) plus periclase; or (4) any combination of them (see Fig. 1). The second possibility has been previously postulated[12].

I have made 12 experimental runs on forsterite in the loading pressure region between 1.5×10^{10} and 3.2×10^{10} Pa and temperatures ~ 900–1,200 °C. The starting material is a synthetic forsterite (Mg_2SiO_4) powder (Tem-pres Research Inc.). The fine polycrystalline sample was mixed intimately with a small amount of powdered graphite, which serves to absorb laser radiation and to heat the sample under compression. The sample was then compressed in a diamond anvil press fitted with a lever and spring assembly and heated by the continuous YAG laser while the sample was maintained at pressure. The

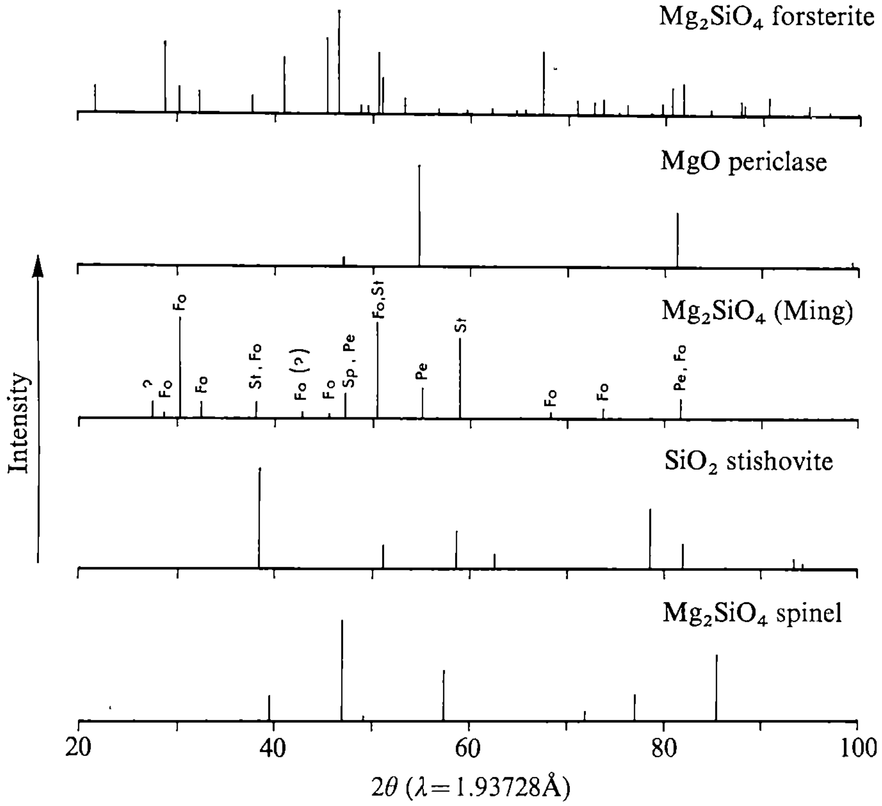

Fig. 2 X-ray diffraction data for forsterite quenched from ~2 5×10^{10} Pa and 1,400 °C (the temperature is highly uncertain) from ref. 14 in comparison with other relevant patterns. Fo, Forsterite; St, stishovite; Pe, periclase.

loading pressures of the sample at the central portion of the anvil were estimated from the length of the spring, and are probably accurate to ±10%. Sample temperatures were estimated to be ~ 1,000 °C with large uncertainty. After quenching and release of pressure, samples were transferred to a modified 57.3-mm Debye–Scherrer camera for X-ray diffraction study. Details of the procedure have been described elsewhere[13].

In the pressure region between 1.7×10^{10} and 2.5×10^{10} Pa (inclusive), nine runs were made at 10^9-Pa intervals; additional runs have been made at 1.5, 2.8 and 3.2×10^{10} Pa. The spinel phase of Mg_2SiO_4 seems to transform directly into a mixture of perovskite ($MgSiO_3$) plus periclase (MgO) at ~ 2×10^{10} Pa. The results obtained at pressures $> 2\times10^{10}$ Pa showed a steady increase of the yield of the perovskite + periclase assemblage with increasing pressure (Table 1). No stishovite, that is, no component oxide mixture, has been identified in the entire pressure region between 1.5×10^{10} and 3.2×10^{10} Pa in this study. These results are in accordance with those of my previous studies on $MgSiO_3$ (ref. 6), but contrast markedly with those reported in refs 1 and 2.

Ming and Bassett[2] did not report the detailed experimental results for Mg_2SiO_4 in their paper, but these data can be found in Table 10 of ref. 14 and have been reproduced graphically here in Fig. 2, together with all the other related phases. In the pattern obtained by Ming, there are only three lines which were attributed to stishovite, but their relative intensities contrast greatly with those for the pattern of stishovite shown in Fig. 2. It is also very surprising that the second intense line of stishovite at 2θ = 78.5° was not observed in Ming's pattern.

Kumazawa et al.[1] reported that forsterite disproportionated into a mixture of stishovite plus periclase on the basis of a single run at 3.3×10^{10} Pa and 1,000 °C for 30 min. (Their pressure should be revised to ~ 2.2×10^{10} Pa and temperature should be much higher (Kumazawa, personal communication).) In none of the present experiments at loading pressures between 1.5×10^{10} and 3.2×10^{10} Pa did I observe the mixed oxide phase assemblage. It is unlikely that the differences in the experimental conditions of pressure and temperature can explain this apparent discrepancy between my results and theirs.

Further support for the present results on the post-spinel phase of Mg_2SiO_4 is provided by studies of the post-spinel phases for 12 silicate and germanate compounds with the olivine stoichiometry in this laboratory. At pressures $> 2.5\times10^{10}$ Pa, only Mg_2SiO_4 Mg_2GeO_4 and Mn_2GeO_4 have been found to transform into the perovskite + rocksalt assemblage. The remainder transform into their component oxides with the rutile and rocksalt structures. The oxide mixture phase assemblage was not found as an intermediate phase between the spinel phase (or the β phase, which is a distorted spinel phase) and the perovskite + rocksalt assemblage in any of the above three compounds.

The associated increase in zero pressure density from the spinel phase of Mg_2SiO_4 to the mixture of perovskite ($MgSiO_3$) plus periclase (MgO) was calculated to be 10.7%. This spinel–post-spinel reaction is characterised by an increase in coordination number of oxygen for Si^{4+} from 4 to 6 and for half of the Mg^{2+} from 6 to 8.

I am grateful to A. E. Ringwood and R. C. Liebermann for comments.

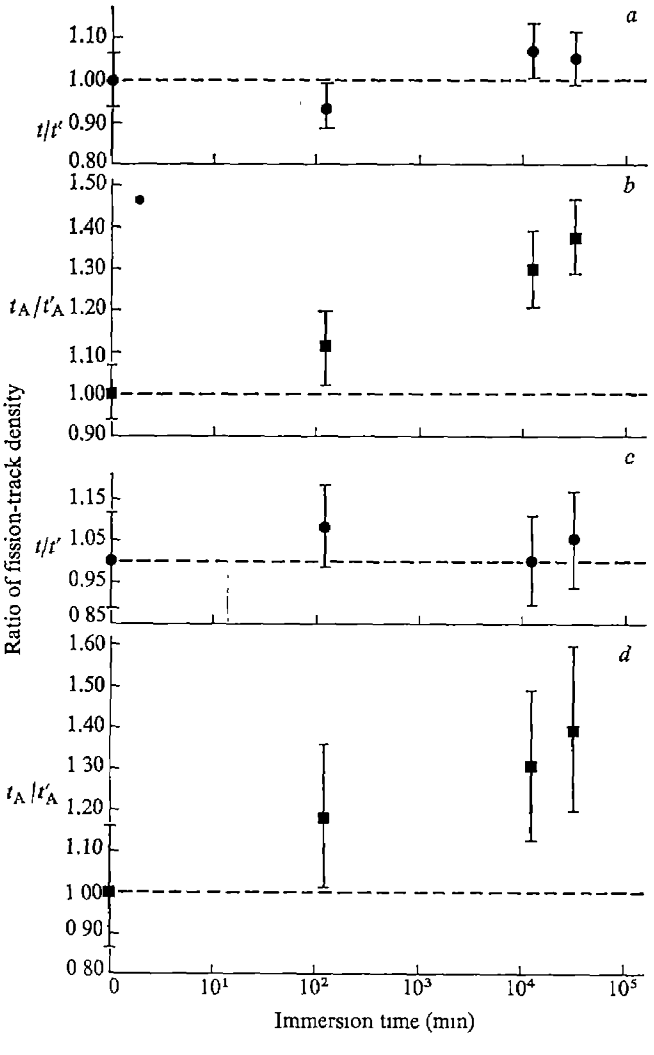
Liquid nitrogen enhancement of partially annealed fission tracks in glass

THE number density of fission tracks in solids is reduced if the sample is heated before chemical etching, and the effect of annealing must be accounted for before an age date can be assigned to the sample[1–3]. The extent of the annealing can be observed by a measurement of the reduction in the track parameters (diameter and/or length) and subsequent comparison to unannealed tracks. Correct ages can be obtained by careful calibration studies of track density reduction against track diameter or length reduction at different annealing temperatures and times[4,5]. For crystalline minerals, however, these correction techniques are not generally valid[6]. In this study, glass samples were partially annealed and then immersed in liquid nitrogen for various periods and we show that the properties of the glass and/or the track parameters can be altered so as to observe tracks that would normally be erased by annealing.

An NBS glass standard (SRM-962) with latent fission tracks was cut in half with a diamond cutting wheel. The exterior surfaces were ground and polished with 12.5-μm and 0.3-μm alumina powder such that at least 30 μm was removed from the surface. The halves were etched simultaneously in 16% HF at room temperature for 75 s and rinsed in warm running water for several minutes. Etched tracks were observed and counted with a Leitz microscope at overall magnifications of 800 and 1,600. The ×800 magnification was used to increase the counting statistics and the ×1,600 was used to identify the fission tracks properly[7]. Track length and width measurements were made at ×1,600 with an eyepiece reticule.

Fig. 1 Track density ratios as a function of liquid nitrogen immersion time. t/t', Track density after immersion/track density at zero immersion time. ● Values found for unannealed sample; ■ values for partially annealed sample.



One of the samples was partially annealed at 230 °C for 1 h. Both halves were ground, polished and etched together as described previously. The track density of the partially annealed sample was found to be half that of the unannealed sample. The length and width of the partially annealed tracks were found to be similarly reduced.

Both samples were then immersed in liquid nitrogen for varying periods At the conclusion of each immersion the samples were polished, etched and counted in the manner described above. The results of the track density measurements against liquid nitrogen immersion time are given in Fig. 1. To compensate for possible variations in etch conditions the ratios of track densities were determined by normalising with the track density having zero immersion time. Figure 1*a* and *c* shows the track ratios against immersion time for the unannealed sample at magnifications of 800 and 1,600 respectively. The ratio remains essentially constant about a value of one. Figure 1*b* and *d* shows the partially annealed track density increasing with immersion time for magnifications of 800 and 1,600 respectively. A gain of ~ 40% was achieved after 760 h of immersion in liquid nitrogen.

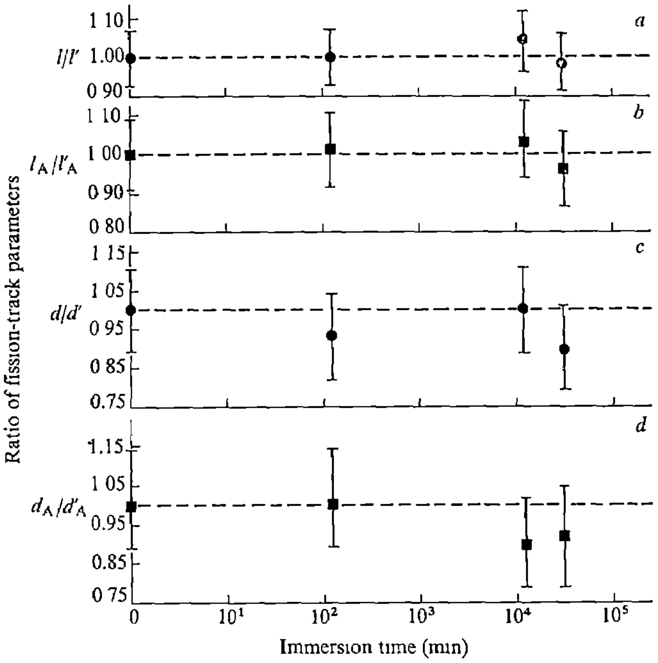


Fig. 2 Track parameter characteristics as a function of immersion time. l/l', Length of track after immersion/length of track at zero immersion time; d/d', diameter of track after immersion/diameter of track at zero immersion time. ●, Unannealed sample; ■, partially annealed sample.

To ascertain whether the track parameters were changing with immersion time, the length and diameter of the tracks were measured after each etching at a magnification of 1,600. Figure 2 shows the ratio of length and diameter for the unannealed (2*a*, *c*) and the partially annealed (2*b*, *d*) samples. For each ratio, the measured quantity with zero immersion time was used to normalise the graphs. The size of the tracks was not noticeably affected by immersion in liquid nitrogen (Fig. 2).

It was thought that thermal shock (room temperature →liquid nitrogen temperature → room temperature) along

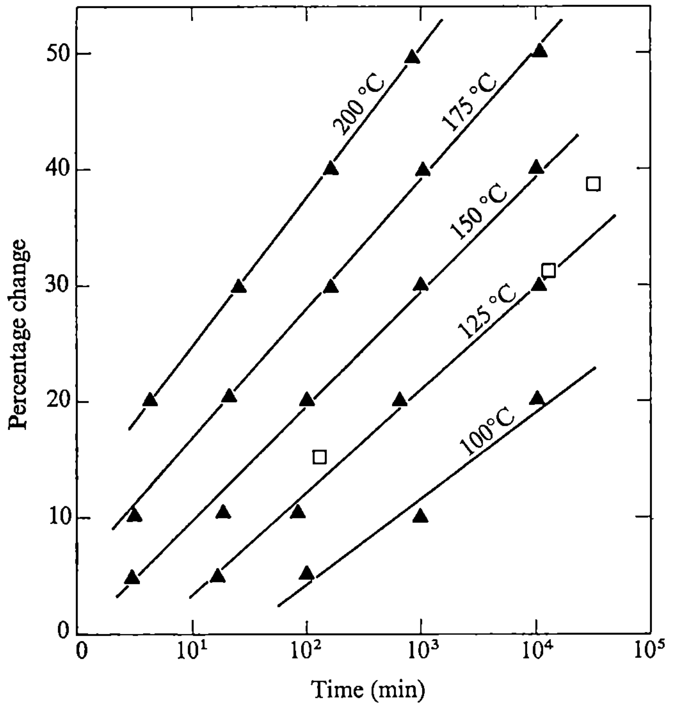

Fig. 3 Percentage change in track density against time for NBS glass standards. □, Percentage track enhancement found in the present study; (——) connecting the points (▲) indicate the percentage track reduction at different annealing temperatures (reported in ref. 8).

the latent track was the cause of the track enhancement. It was found, however, that repeated (four times) immersion of the samples in the liquid nitrogen (for 2 h) did not lead to an increase in the track density.

A recent study[8] of the thermal stability of fission tracks in NBS glass standards reported a track density decrease with increasing annealing time and temperature. The percentage track reduction at different annealing temperatures and times from that investigation are replotted in Fig. 3, together with the average gain (×800 and ×1,600 magnifications) against immersion time obtained in the present study. The slopes of the annealing plots and liquid nitrogen immersion plot seem to be compatible. This suggests that the mechanism which erases the track damage through annealing may be partially reversed when the temperature of the sample is significantly lowered for a sufficient length of time. Further work is under way (at different immersion temperatures and partial annealing conditions) to test whether or not the process of enhancement is a reversal of the annealing process. Similar enhancement effects using liquid nitrogen have been found for α-particle tracks in polycarbonate detectors and those results will be published.

Although the mechanism of track reduction with temperature rise (annealing) is not clearly understood[7], track enhancement by cooling may provide a new avenue of research into this problem In addition, this method has possible application in dating geological samples partially annealed by post-emplacement thermal events.

Direct measurement of long range forces between two mica surfaces in aqueous KNO$_3$ solutions

We have constructed an apparatus for measuring the forces between two surfaces immersed in a liquid directly as a function of separation, and report initial results for the forces between two crossed cylindrical sheets of molecularly smooth muscovite mica in aqueous solutions of KNO$_3$.

The apparatus is shown schematically in Fig. 1. It is similar to earlier models used for measuring the van der Waals' forces between two freshly cleaved mica sheets in air *in vacuo*[1,2]. The present apparatus has been refined to allow for the measurement of the very different types of forces in the conditions that occur in liquids. Multiple beam interferometry is used for measuring the shape of the surfaces and their separation to within 0.1 nm (ref. 3). The separation between the two surfaces is controlled by a three-stage mechanism: an upper micro-driven rod (to $\sim$1 µm), lower micrometer-driven rod (to $\sim$ 1 nm) and a piezoelectric crystal (to < 0.1 nm). The lower rod operates by a differential spring mechanism· the double cantilever spring is about a thousand times stiffer than the helical spring so that a 1-µm movement of the motor-driven lower rod is reduced to a 1-nm movement between the two mica surfaces. All parts of the apparatus are made of 316 stainless steel, Teflon, Delrin and glass. Extreme precautions were taken to purify the water and potassium nitrate, and a high degree of surface cleanliness was maintained in the equipment. The apparatus is suspended by springs to isolate it partially from extraneous vibrations. Some residual vibrations of the surface (a few Å) was found to be an asset, in that it indicated that the surfaces were truly separated and not in contact through a dust particle or a mica flake In view of the repulsive forces measured, this precaution was essential, since a minute particle between the surfaces far from the region of closest approach could go undetected and lead to a spurious repulsion being measured.

In the present set-up the glass disk supporting the lower mica sheet was suspended at the end of a cantilever spring of stiffness $\sim 10^2$ N m^{-1}. The forces were measured by applying a sudden voltage to the piezoelectric crystal, which causes it to expand or contract by a known amount, say 10 nm. The resulting change in the separation between the two surfaces is then measured optically and any difference in the two values, when multiplied by the stiffness of the single cantilever spring, gives the force difference, whether attractive or repulsive, between the initial and final separations. In this way, forces may be measured at any separation down to contact.

Figure 2 shows some of these results for mica in KNO$_3$ solutions at 20 °C, pH$\sim$6. The repulsive forces were all found to be exponential, with a decay length close to the Debye length. Below a certain separation, however, the repulsion increased more rapidly. The onset of this enhanced repulsion occurred very roughly at about half a Debye length separation. The magnitude of the repulsive forces was found to be different for the different mica samples used. In 0.1 M and 1 M solutions the onset of repulsion was preceded by an attractive region for those samples in which the repulsion was weak, thereby indicating the existence of a secondary minimum at these concentrations. It

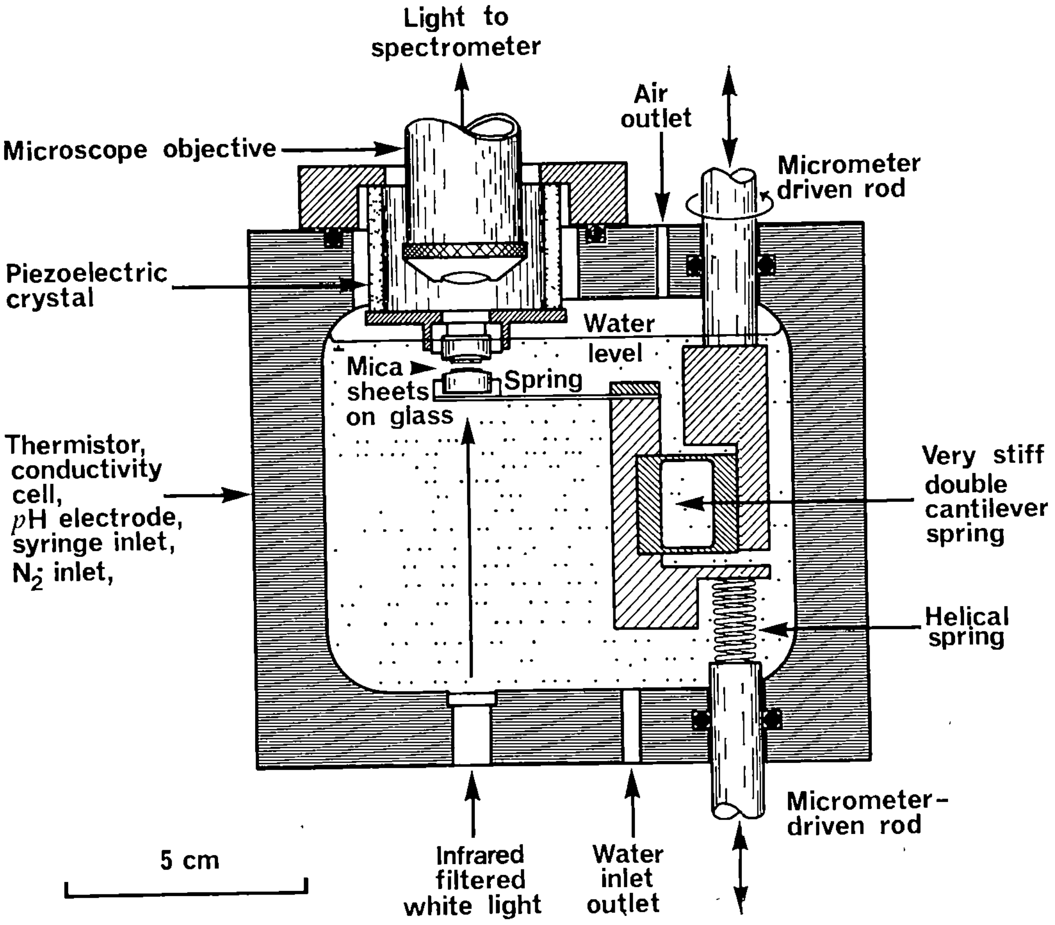

Fig. 1 Schematic drawing of apparatus to measure long range forces between two crossed cylindrical sheets of mica (of thickness ~ 1 μm and radius of curvature ~ 1 cm) immersed in liquid. By use of white light and multiple beam interferometry the separation between the two mica surfaces may be measured to ~ 0.1 nm. The separation between the two mica surfaces may be controlled by use of two micrometer-driven rods and a piezoelectric crystal to better than 0.1 nm.

was also observed that the repulsion was irreversibly reduced after the surfaces had been brought very close together (<4 nm), reminiscent of qualitatively similar observations on aqueous dispersions of sodium montmorillonite sheets in NaCl solutions[4,5]. At larger separations, however, the results were reversible and reproducible and clearly exhibit all the essential features of a DLVO-type interaction involving repulsive double layer forces and attractive van der Waals' forces[6,7]. In particular, we note that even in 0.1 M KNO_3 the decay length of the exponential repulsive region is equal to the Debye length (~1 nm) indicating that the Poisson–Boltzmann equation, at least for KNO_3, seems to remain valid even at this high concentration. The observation that at separations smaller than the Debye length the repulsive forces increased even more rapidly is qualitatively consistent with theoretical predictions of double-layer forces based on the nonlinear Poisson–Boltzmann equation[8]. The magnitude of the attractive forces in the region of the secondary minimum is of the order to be expected from the general theory of van der Waals' forces.

It is difficult to say without more detailed analysis, whether at very small separations, <1 nm, there is also a primary minimum, since at these separations the mica sheets have deformed appreciably under the influence of the strong forces. Tearing of mica was, however, often observed on separation after very close approach, thus indirectly pointing to the existence of strong adhesion at or near contact. The lack of a clear-cut turnover in the force into a primary minimum is consistent with previous measurements on the interactions between other silicate sheets[4,5], as well as the observation that silica dispersions are sometimes stable at very high electrolyte concentrations and undergo reversible coagulation[9].

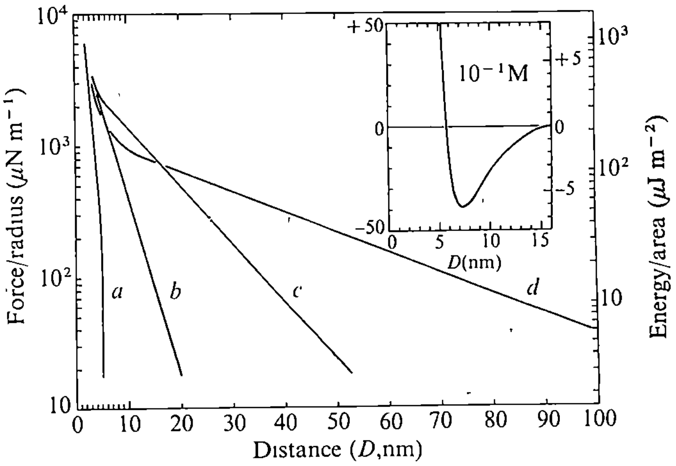

Fig. 2 Experimental results of direct measurement of force as a function of separation between two crossed mica cylinders of radius R in various KNO_3 solutions. The right-hand ordinate gives the interaction energy per unit area for two parallel plates, calculated according to the 'Derjaguin approximation'[7]. The ordinate of the inset is linear. The magnitude of the repulsive forces was found to be different for different mica samples. The results shown here are for those samples in which the repulsion was relatively weak and where a secondary minimum was clearly observed. The scatter in the experimental points is ~ 10 μN m⁻¹ for the force/radius. *a*, 10^{-1} M; *b*, 10^{-2} M; *c*, 10^{-3} M; *d*, 10^{-4} M.

We thank Dr T. W. Healey, Professors R. J. Hunter and B W. Ninham for helpful discussions, Mr P. East for machining, and Mr J Gascoigne for technical assistance.

Axial, magnetron, cyclotron and spin-cyclotron-beat frequencies measured on single electron almost at rest in free space (geonium)

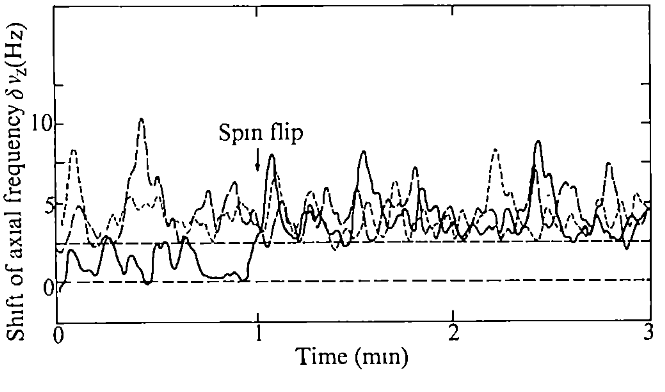
THE monoelectron oscillator[1] consists of a ~ 1-meV electron contained in a weak electric quadrupole field plus strong axial magnetic field (the Penning trap) on which the axial oscillation is continuously observable. It may profitably be looked on as an ultraheavy metastable pseudoatom, 'geonium' (through the trap and the magnet, the electron is bound to the Earth ultimately). The energy levels are given by[2]

$$h^{-1}E_{\mathrm{mnkq}} = m\nu_{s}+(n+\tfrac{1}{2})\nu_{c}+(k+\tfrac{1}{2})\nu_{z}-(q+\tfrac{1}{2})\nu_{m}$$

$$m = \pm\tfrac{1}{2};\, n = 0,1,2,3\ldots ;\; k = 0,1,2,3\ldots ;\; q = 0,1,2,3\ldots$$

with $\nu_c = eH/2\pi mc$, $2\nu_c\nu_m - 2\nu_m{}^2 = \nu_z{}^2$. We report here the measurement of the axial, magnetron, cyclotron, and spin-cyclotron-beat frequencies ν_z, ν_m, $\nu_c-\nu_m$ and $\nu_s-\nu_c+\nu_m$ using this apparatus, held at 4 K. A new axial-frequency-shift technique using a 30-gauss deep magnetic bottle superimposed on the 18-kgauss field supplied by a superconducting magnet was used for the last two frequencies. The road to this advance was paved by two developments, namely the anharmonicity compensated trap[3] yielding an axial line width of 10^{-7} and the "entropy reduction by motional sideband excitation" (ref. 4) method. The latter allows the centring of an electron liberated in the trap to close tolerance guaranteeing the constancy of ν_z.

Fig. 1 First spin flip seen in the monoelectron oscillator (geonium). Because of the random fluctuations in the thermally excited cyclotron motion, the axial frequency shift $\delta\nu_z$ associated with the magnetic bottle shows a corresponding unsymmetric fluctuation always staying above a fixed floor for a given spin direction. This floor, however, suddenly changes by 2 5 Hz when the spin is flipped, which occurs occasionally near resonance, $\nu_z-\nu_d \simeq 2$ *k*Hz. No auxiliary drive was used. Three superimposed traces are seen, only the heavy one showing the spin flip.



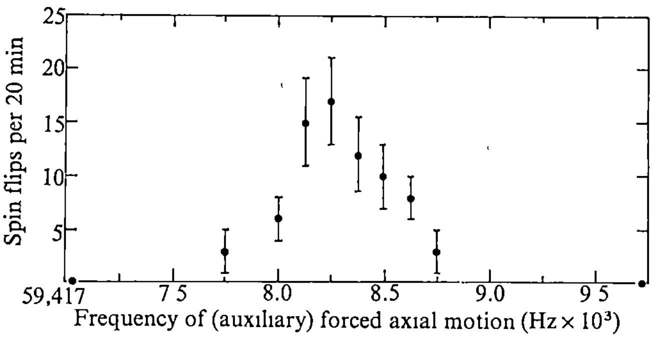


Fig. 2 Resonance at the spin-cyclotron-beat frequency ν_d in geonium. The auxiliary axial drive amplitude has been adjusted thus, that spin flips occur no faster than 1 min^{-1}, and can be conveniently counted in 20-min periods, during which the auxiliary drive frequency is kept constant. Data from a later run are shown.

Essentially as proposed by us[5-7], the resonance at $\nu_d = \nu_s - \nu_c + \nu_m$ was observed by making the electron see an effective, adjustable (< 10 μgauss) rotating magnetic field at ν_s, the spin frequency, occurring as the sum of an (auxiliary) forced axial motion frequency ν_d = 59.415890 MHz and $\nu_c - \nu_m \simeq 51206.11$ MHz, the frequency of the thermal cyclotron motion through the inhomogeneous static field of the magnetic bottle. Spin flips, thereby induced at a rate of 1 min^{-1}, were detected by continuously monitoring the bottle-related shift $\delta\nu_z \simeq (m+n+\tfrac{1}{2})$ 2.5 Hz of the axial resonant frequency ν_z = 59.4101 MHz and focusing on the minimum values, 2.5 and 0 Hz, corresponding to $n = 0$, $m = \pm\tfrac{1}{2}$, which occur as the electron jumps frequently between the cyclotron levels, *n*, and rarely between the spin levels, *m* (Fig. 1).

The minimum ν_d linewidth of ~500 Hz realised so far (see Fig. 2), arises primarily from the continuous ν_z monitoring. Pulsed operation promises a 100-fold sharper line. With the measured ν_m = 34.464 kHz, our preliminary value of $a \equiv (\nu_s - \nu_c)/\nu_c$ is 0.001159655(5). This agrees with the theoretical value[6] for $(g-2)/2$ quoted with an error ten times smaller. The empirical dimensionless ratio *a* can contain information only on the structure of the electron. Just as in an atom the experimental *g*-factor provides an important check on the 'purity' of an actual stationary state when expanded after states of an approximate Hamiltonian, thus *a* is a measure of the contribution to the actual electron wave function by other elementary particles which, together with the Dirac electron, may all be considered as stationary states of the same approximate Hamiltonian describing the spectrum of matter–energy. As a consequence, useful bounds are put on weak interaction models[9].

Entropy reduction by motional sideband excitation

EVERYONE is intuitively familiar with the second law of thermodynamics: the disorder in any closed system can only increase with time. A familiar example is the spreading of a scent through a room. It is also well known that the spreading greatly accelerates when exterior agents are at work, for example, a stirrer. The reverse task of 'bottling up' the diffused scent back in the flask from which it expanded is much more difficult. So if one had somehow succeeded in collecting a cloud of particles in a vacuum at the bottom of a suitable potential well, as would be desirable in removing Doppler shifts in coherent spectroscopy or even in nuclear fusion machines, there will be all sorts of effects at work to spread the particles out again. The principle of entropy reduction by motional sideband excitation[1] could be effective in re-collecting the spread out cloud at the bottom of the well.

As a specific example, consider an atom emitting optical radiation at ν_1 while vibrating in a translational mode at a radiofrequency ν_v in a parabolic well. Because of the Doppler effect, the optical radiation will then be frequency modulated at the radiofrequency ν_v. This implies that its spectrum will consist of a carrier at ν_1 and symmetric sidebands spaced at the radiofrequency ν_v. Inversely, if the vibrating atom is irradiated at one of the spectral optical components, say at the one at $\nu_1 - \nu_v$, it will be optically excited and will in turn radiate symmetrically at all the frequencies ν_1, $\nu_1 \pm \nu_v$, $\nu_1 \pm 2\nu_v$ . . . . So, while absorbing quanta of energy $h(\nu_1 - \nu_v)$ it will radiate quanta of average energy $h\nu_1$, that is, larger by $h\nu_v$. This incremental energy can only come from the translational vibrational motion in the well, which is thereby reduced, bringing the atom closer to the centre of the well and possibly completely freezing out the quantised vibration. The principle is equally effective if the sidebands are created by amplitude modulation caused by motion through an inhomogeneous alternating field. The latter effect has, in fact, recently been demonstrated on a single electron confined in a Penning trap in ultra high vacuum. In such an axially symmetric trap, the electron is axially contained by an electric parabolic well while the corresponding radial potential hill is effectively overcompensated by an axial magnetic field. The guiding centre of the small diameter cyclotron orbit carries out a circular magnetron motion at $\nu_m \simeq \nu_z^2/2\nu_c \simeq 80$ kHz for an axial frequency $\nu_z \simeq 60$ MHz and a cyclotron frequency $\nu_c \simeq 20$ GHz. When the moving electron is now subjected to an axial r.f. field at ν_{zd} varying along the magnetron orbit, the electron will see spectral components at ν_{zd}, $\nu_{zd} \pm \nu_m$, $\nu_{zd} \pm 2\nu_m$. If one now chooses $\nu_{zd} = \nu_z + \nu_m$ the damped axial oscillation at ν_z will be excited. Hereby the energy excess $h\nu_m$ per absorbed $h\nu_{zd}$-quantum will be used to move the electron up the radial electric potential hill until it reaches the axis. This effect and also the inverse one, namely rapid increase of the magnetron motion radius for excitation at $\nu_{zd} = \nu_z - \nu_m$, has recently been demonstrated by Van Dyck *et al.*[2]. Monitoring the radial coordinate, r, of the electron was made possible by the presence of a small anharmonic term in the electric trapping potential which made ν_z a weak function of r.

The low frequency dielectric constant of supercooled water

THE extension of computer dynamical calculations of water structure[1] to temperatures < 0 °C has encouraged speculation that the supercooled liquid might exhibit ferroelectricity. The discovery that, by use of surfactants such as sorbitan stearates, water can be emulsified[2] in hydrocarbon solvents and then readily supercooled, opens up extensive new fields of experimentation. We have measured at 1,652 Hz the real part of the low frequency permittivity of 0.5% and 1% water emulsions down to −36 °C and thence calculated the real part of the dielectric constant of liquid water, which is essentially static in this range of frequency and temperature. The values, shown graphically in Fig. 1, lie on a smooth curve and compare with data for polycrystalline ice[3]; no ferroelectric transitions are observed.

Emulsions of deionised water were made in *n*-hexane using as emulsifier polyoxyethylene sorbitan tristearate (Tweens 65, from Honeywell-Atlas, Ltd); these were cooled and measurements made in a temperature-controlled refrigerator. The mean diameter of the water spheres was found by microscopy to be ~ 40 μm, but the spread is an order of magnitude in each direction. The Wayne-Kerr D121 permittivity cell and General Radio GR1621 precision measurements system were used. At each volume concentration, including 0% water with emulsifier present, three measurement runs were taken at 2 °C intervals, and the mean value of the mixture permittivity ε_m taken.

According to the Maxwell–Lewin dielectric mixture formula[4] for a volume fraction, ν, of spheres of substance 1 (water) in a matrix of substance 2 (*n*-hexane)

$$\frac{\varepsilon_m - \varepsilon_2}{3\varepsilon_2} = \nu \left[\frac{\varepsilon_1 - \varepsilon_2}{2\varepsilon_2 + \varepsilon_1} \right]$$

Since in the temperature range 0–20 °C the low frequency permittivity of water ε_1 is known accurately[5], the formula can be fitted to the best value of ν, taking for ε_2 the present 0% data. The value of ν is found to be within 0.7% of the volumetrically-determined value over the 0–20 °C range; there are a number of errors and effects contributing to this apparent volume defect, including the molar volume of the surfactant molecules. Assuming the value of ν calculated thus to be independent of temperature, ε_1 can be calculated from the data at temperatures ⩽ 0 °C. The consistency between the 1%

Fig. 1 The temperature dependence of the real part of the dielectric constant of water. ○, 1% volume fraction emulsion; ●, 0.5% emulsion.

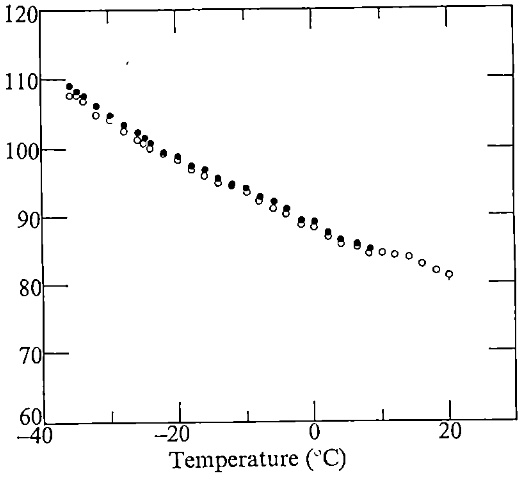

Table 1 Best values for temperature dependence of the permittivity of water

T(°C)	ε (water)
−35	107.7
−30	104.2
−25	100.8
−20	98.3
−15	95.6
−10	93.4
−5	90.9

and 0.5% data in Fig. 1 is such that ± 2% confidence limits might be placed on the mean of the two sets. The neglect of the temperature variation of ν from thermal expansion gives rise to a positive error of 0.2% at −35 °C, with correspondingly smaller errors at higher temperatures. Neglecting these errors, the best values are given in Table 1. They fall well outside the polynomial fit to the data that has been made at temperatures ⩾ 0 °C (ref. 5), a feature of supercooling which has been noted in other polar liquids[6].

There is apparently very little Maxwell–Wagner effect arising from conduction processes. A detailed study of the dielectric relaxation processes in the supercooled state is planned.

Conformation of Met^5-enkephalin determined by high field PMR spectroscopy

THE discovery by Hughes *et al.*[1] that peptides (the enkephalins) could be the endogenous agonists of opiates in brain represents a challenge to medical chemistry both in its fundamental aspects and for the possible development of new therapeutic approaches. To understand how non-peptidic substances belonging to various chemical classes can mimic the action of the pentapeptide enkephalins it is first necessary to determine the spatial arrangement of the latter. We have thus synthesised large quantities of Met^5-enkephalin (H–Tyr–Gly–Gly–Phe–Met–OH) and determined its preferential conformation in solution using high field proton magnetic resonance (PMR) spectroscopy at variable temperatures, coupling constants in relation with Karplus–Bystrov curves[2] and conformational energy steric maps[3].

The most characteristic features of this conformation, which could account for some of the physicochemical and biological properties of the molecule seem to be: (1) a highly folded structure; (2) a precise homology between morphine and Met^5-enkephalin as regards their respective functional groups (the phenol ring corresponding to the Tyr residue and the tertiary amine corresponding to the terminal ammonium function of the peptide); and (3) a relative freedom of the N-terminal peptide Tyr–Gly.

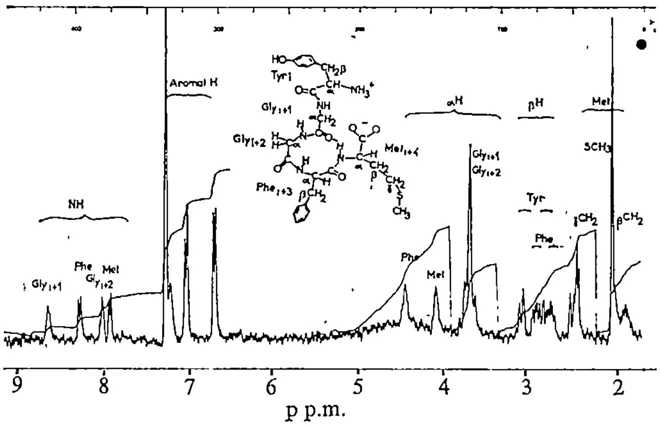

Fig. 1 300-MHz spectrum of Met^5-enkephalin (5×10^{-1} M) in DMSOd$_6$. Probe temperature, 17 °C. TMS as internal reference.

Met^5-enkephalin was prepared by liquid phase synthesis (unpublished). Its 300-MHz PMR spectrum was recorded in DMSOd$_6$ in which it dissolves readily (Fig. 1). All the $^3J_{NH-CH\alpha}$ and $^3J_{CH\alpha-CH\beta}$ have been measured experimentally and the most probable values of torsional angles φ and ψ were determined from the Karplus–Bystrov curves and conformational energy steric maps, respectively. The chemical shift variation of the Met NH proton, as a function of temperature, is somewhat lower than that of the other NH protons of the molecule, suggesting that this proton is involved in a hydrogen bond or is in a buried position. Only minor changes in coupling constants were observed with temperature variation, indicating that in the present conditions, the conformation is well defined, and corresponds to a relatively deep energy well. The conformational behaviour of Met^5-enkephalin in aqueous medium also parallels very closely that found in DMSO (our unpublished results). On the basis of these results, we propose the conformation reported in Fig. 2 with a β_I turn[4] involving the sequence Gly–Gly–Phe–Met and a hydrogen bond between the NH of the Met$_{i+4}$ and the CO of the Gly$_{i+1}$ following the Tyr residue. In this conformation, the two aromatic residues (Tyr and Phe) are pseudoequatorial and the side chain of Met is pseudoaxial to the mean plane of the peptide backbone.

Interestingly, in this structure, the three hydrophobic chains (Tyr, Phe, Met) are situated at the periphery of the pseudocycle of the β_I turn and the NH$_3^+$ and the COO$^-$ terminal groups exhibit a spatial proximity (end-to-tail interaction). These

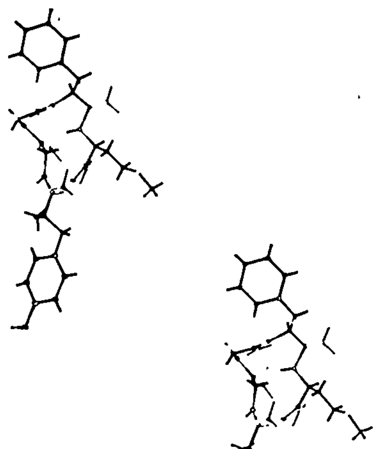

Fig. 2 Representation of the characteristic parts of opiates (left) and opiate-like peptides (right) exhibiting structural homology.

features probably account for the marked hydrophobic properties of Met^5-enkephalin (water solubility < 0.7%), which suggest that the peptide could cross lipid-containing membranes with relative ease, including the so-called 'blood–brain barrier', a property which might be of considerable therapeutic interest.

The conformation of Met^5-enkephalin deduced experimentally from its spectra in solution is different from the hypothetical conformation recently proposed[6] and characterised by a β turn involving a hydrogen bond between the CO of the Tyr residue and the NH of the Phe residue. Nevertheless, the preferential conformation of Met^5-enkephalin that we propose also shows all the steric requirements found in morphine for a stereospecific interaction with the receptor. In the N-terminal part of the molecule, the distance between the OH phenolic group and the ammonium function are the same, namely 6.8 Å, in morphine and in the proposed conformation of Met^5-enkephalin (Fig. 3). Moreover, the spatial orientation of the ammonium groups in respect to the phenol rings is similar in both compounds.

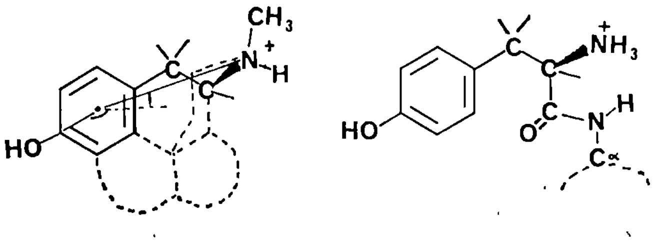

Fig. 3 Stereoscopic view of enkephalin along the mean plane of β_I turn with $\psi_i=0°$ (to allow for end-to-tail association), and $\varphi_{i+4}=-160°$ (avoiding steric strain for the side chain of methionine). Carbonyl peptide functions are visualised by bend bonds, C–N bonds are recognised by their change in colour (black–grey). The head (Tyr) is at bottom right, the tail (Met) at top right. The methionine side chain is pointing towards the observer (axial character); that of Phe has a pseudo-equatorial character. The aromatic rings are almost coplanar to the β_I turn. Typically, NH_{i+4} is the only peptide NH proton pointing inwards.

The structural analogies between Met^5-enkephalin and opiates suppose the existence of the opiates in the protonated form at physiological *p*H. Any modification of the N-terminal Tyr leading to a non-protonated form at this position should therefore inhibit biological activity. This assumption seems to be substantiated by the observation that substitution of the N-terminal function of the Tyr residue in opiate-like peptides leads to a loss of affinity for the receptor[6].

In addition, it should be stressed that the β_I turn gives a large degree of freedom to the Tyr–Gly moiety towards the rest of the molecule and this could be of importance in understanding the activity of other peptides with opiate-like activity. The primary attachment of Met^5-enkephalin to the receptor could conceivably involve the Tyr–Gly moiety and the relative freedom of this moiety would allow the secondary attachment of the hydrophobic part of the molecule. It can be assumed that similar features (presence of an N-terminal Tyr–Gly moiety in a state of relative freedom) could account for the common affinity of many peptides like the two enkephalins, lipotropin C and the synthetic compounds of Goldstein *et al.*[6]. The relative differences in affinity between these compounds would depend essentially on the secondary interactions (for example, hydrophobic, hydrogen bond). The decreased affinity in Leu^5-enkephalin compared with Met^5-enkephalin[1] could thus be attributed to the loss of a hydrogen bond involving the sulphur atom of the Met residue.

It is hoped that these features of enkephalins will facilitate synthesis of opiate-like peptides of high potency and appropriate pharmacological properties, particularly in connection with the search for a non-addictive analgesic[7].

Proton magnetic resonance studies of conformation and flexibility of enkephalin peptides

ENKEPHALIN, an endogenous pentapeptide which has the analgesic properties of morphine[1], has recently been isolated, purified and characterised both chemically and pharmacologically[2,3]. The fact that enkephalin and the opiates interact with the same receptor raises the possibility that the similarity in their function might be based on common structural features[4,5]. Particular attention has been paid to the geometric relationship between the aromatic ring of the tyrosine residue and the terminal amino group of enkephalin compared with the known geometry of similar functional groups in morphine. The relative spatial disposition of the phenylalanine and tyrosine aromatic side chains is also of special interest because of the possible resemblance of enkephalin to oripavine[4,5]. So far, however, no experimental determination of conformational parameters has appeared. Here we report proton magnetic resonance (PMR) studies of Met^5-enkephalin which indicate that the methionine amino proton is involved in a hydrogen bond, most probably within a Gly–Gly–Phe–Met type I β turn, but not with a turn involving Tyr–Gly–Gly–Phe as proposed previously[6]. Although our data exclude a γ turn, they do not rigorously exclude other conformations, especially if these have small statistical weights.

Assignments of the 270-MHz PMR spectrum made by double resonance and difference double resonance are shown in Fig. 1. The only possible ambiguity in assignment, distinguishing Gly_2 and Gly_3, was removed by titration from $^2H_6$-DMSO into ^2H_2O, the assignments in ^2H_2O having been previously made by *p*H titration. The chemical shifts and scalar coupling constants obtained by spectral analysis are shown in Table 1. The side-chain rotamer populations derived from these are also listed.

It has been demonstrated[7,8] that very small temperature dependencies such as observed here for Met (Fig. 2) are strong evidence for a hydrogen bond involving that amide proton. The coupling constants ($^3J_{NH-CH}$) in Table 1 enable us to rule

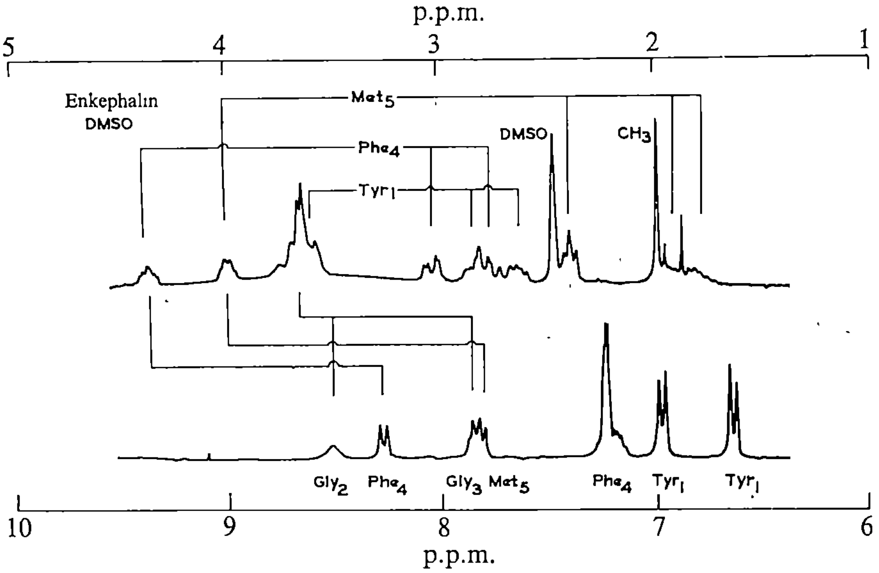

Fig. 1 PMR spectrum of Met^5-enkephalin in $^2H_6$-DMSO. The Tyr$_1$-OH and NH$_3$ signals are not present and the Gly$_2$-NH is broadened. Scale is p.p.m. from HMS.

out the possibility that the hydrogen bond is involved in a γ turn[9] and are instead indicative of a type I β turn. A type II β turn would not be in such good agreement with the observed coupling constants as a type I β turn but cannot be rigorously excluded by these data. Further studies of the Gly$_2$ and Gly$_3$ residues are needed since accidental degeneracy of the C_α protons has so far prevented an analysis of the NH–CH$_2$ spin system of Gly$_3$, and since the two $^3J_{NH-CH}$ values for Gly$_2$ are not available from the spectrum because of line broadening. A similar line broadening has been observed in oxytocins[10].

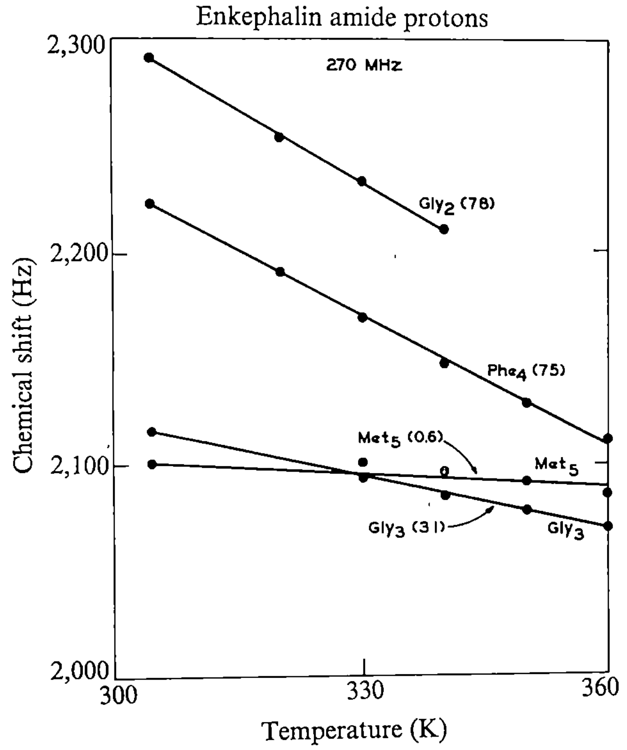

Fig. 2 Effect of temperature on the amide proton chemical shifts. The slopes (p p.10^9 per °C) are given in parentheses.

The analysis of the side-chain rotamer population[11] (Table 1) shows that the Met, Phe, and Tyr side chains favour one of the two possible *trans–gauche* rotamers[12], but for each of these residues all three rotamers have significant populations. Two conclusions can be drawn from this fact. First, there are $3^3 = 27$ possible forms of enkephalin which differ in the orientation of at least one of these three side chains. Second, for each of these three amino acids the Boltzmann energy differences (ΔE) between the various rotamer states must all be $\sim RT$. Consequently, we conclude that there may not be a simple direct relationship between the rotamer preferences observed here and the side-chain conformation on the receptor. Note, however, that a *trans–gauche* isomer of tyrosine (Table 1) is required to give a tyrosyl geometry resembling morphine.

Clearly, the more stable a conformational feature is, the more likely it is to be preserved in the substrate–receptor complex. Since β turns are often stabilised to the extent of several kcalories, the β turn which we are suggesting for the solution conformation of enkephalin may be an important feature in the interaction of enkephalin with its receptor. There are two pieces of indirect evidence which support this. First, a model of enkephalin in a type I β turn involving the Met–Phe–Gly–Gly residues shows a distinct topological resemblance to oripavine in the relative disposition of the tyrosyl and phenyl rings. The importance of the conformation of the β turn and Phe is clearly shown by the fact that the replacement of L-Phe by D-Phe in Met^5-enkephalin results in a peptide which is inactive (Garsky *et al.*, unpublished). Although a β turn of the residues Tyr–Gly–Gly–Phe (ref. 6) also resembles oripavine, the chemical shift data in Fig. 2 show no evidence for a hydrogen bond between the amino proton of Phe and the carbonyl group of tyrosine[6]. Second, the side-chain rotamer populations of Phe exhibit the normal tendency toward $a = b = c = 1/3$ as temperature is increased (Fig. 3). This behaviour is indicative of a situation in which there is only one degree of rotational freedom (that is, the rotation about the C_α–C_β bond in this case) which has Boltzmann energy differences $\Delta E \sim RT$ and is the behaviour we find in other peptides with rigid ($\Delta E > RT$ backbone structures. In contrast, non-rigid backbones ($\Delta E \sim RT$) would be expected to add considerable complexity to the temperature dependence of side-chain rotamer populations. As Fig. 3 shows, both the Met and Tyr side-chain rotamer populations show a less conventional temperature dependence than Phe and this may indicate greater flexibility for the φ, ψ angles of Met and Tyr than for the corresponding angles involved in the β turn.

Our data are consistent with a backbone conformation of enkephalin having a type I β turn with a hydrogen bond between the amide proton of Met$_5$ and Gly$_2$ (Fig. 4). Correlation of this conformation and that of morphine with their respective biological functions is not simple. The predominant *trans–gauche* geometry of the Tyr$_1$ residue certainly correlates

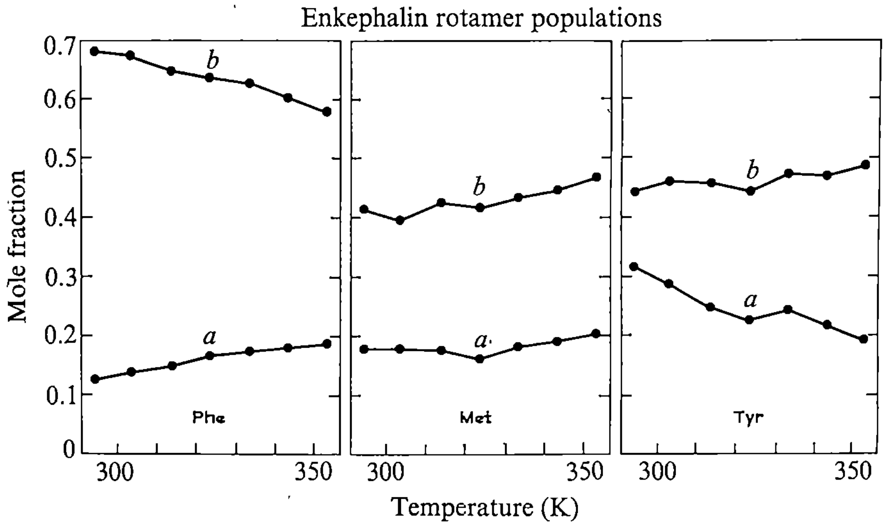

Fig. 3 Effect of temperature on the rotamer populations of Met^5-enkephalin (calculated by the method of Pachler[11]). The third rotamer population can be obtained from the graphs, since $a+b+c = 1$.

with the known steric requirements of morphine[4,13], but there is not yet a simple explanation of the requirement for a type I β turn (except that L-Phe and not D-Phe is active) or that there can exist 27 rapidly interconverting enkephalin forms. The time scale for this rearrangement will be approximately 10^{-10}–10^{-11} s, which is faster than the residence time of the hormone–receptor complex. Consequently, all 27 enkephalin forms may bind initially to the receptor which then selects the appropriate form in accordance with the induced-fit theory of hormone action[14].

In H_2O solution, both Gly_2 and Gly_3 $NH–CH_2$ spin systems are degenerate as $^2H_6$-DMSO and the Phe_4 and Met_5 have $^3J_{NH-CH}$ values close (1 Hz) to the value in $^2H_6$-DMSO. The interpretation of these data is that the enkephalin conformations and internal motions are qualitatively similar in both solvents. Leu^5-enkephalin has basically the same conformation as Met^5-enkephalin in $^2H_6$-DMSO.

Mode of deactivation of the enkephalins by rat and human plasma and rat brain homogenates

SEVERAL groups of workers have recently demonstrated the existence of naturally-occurring peptides which show agonist activity at the opiate receptor[1-4], and Hughes *et al.*[5] have shown that the opiate activity isolated by them is due to a mixture of two peptides H-Tyr-Gly-Gly-Phe-Met-OH and H-Tyr-Gly-Gly-Phe-Leu-OH termed methionine-enkephalin and leucine-enkephalin respectively.

The agonist activity of these two peptides was established using *in vitro* techniques and early work[2] demonstrated that the enkephalins were subject to rapid deactivation when exposed to tissue homogenates and purified enzyme preparations such as carboxypeptidase-A and leucine aminopeptidase. In view of these results, it was perhaps not surprising to find that *in vivo*, even after central administration, the antinociceptive actions of the peptides are, at best, transient (refs 6 and 7 and G. Metcalf, personal communication). Using the depressant effects of the enkephalins on the electrically-evoked contractions of the mouse vas deferens as a bioassay, the half-life of both peptides in rat plasma was shown to be very short (Table 1). In this study we attempted to identify the mode of deactivation of the peptides in rat plasma and brain homogenates, which we believe could be responsible for the limited *in vivo* activity of the enkephalins.

^{3}H-Gly^3-Met^5-enkephalin was synthesised from ^{3}H-glycine using solutions methods[15] 3,5-^{3}H-Tyr-Leu^5-enkephalin was synthesised from the unlabelled pentapeptide by the Radiochemical Centre, Amersham.

Met^5-enkephalin, Leu^5-enkephalin, H-Tyr-Gly-Gly-Phe-OH, H-Gly-Gly-Phe-Met-OH, and H-Gly-Gly-Phe-Leu-OH were synthesised by standard methods[15]. Thin-layer chromatography was carried out on silica plates (Keiselgel F_{254}, Merck Ag) using the following solvent systems: (1) chloroform–methanol–acetic acid–water, 45:30:6:9 (2) *n*-butanol–pyridine–acetic acid–water, 60:20:6:24 (3) *n*-butanol–ethyl acetate–acetic acid–water, 1:2:1:1 (4) chloroform–methanol–acetic acid, 18:2:1. Distribution of radioactivity on the plates was determined using a zonal scraping technique. Column chromatography was carried out on DEAE–Sephadex in the acetate form with 1% pyridine, 0.04% acetic acid as eluting solvent. Peptides were hydrolysed in 6 M hydrochloric acid in sealed tubes (108 °C; 20 h) before analysis using a Jeol 6 AH automatic amino acid analyser.

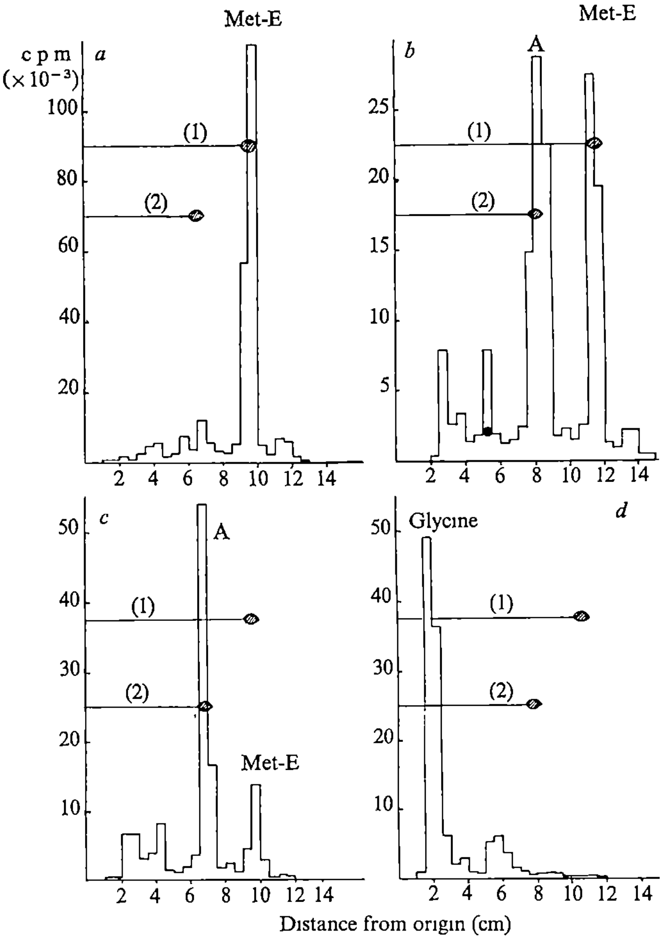

Fig. 1 Breakdown pattern of ^{3}H-Gly^3-Met^5-enkephalin (0.3 × 10^{-6} M) at 37 °C by rat plasma (20% v/v) in 50 mM Tris-HCl buffer (*p*H 7.4). *a*, 0 min; *b*, 5 min; *c*, 10 min; *d*, 30 min. Samples (0.2 ml) were taken periodically, added to methanol (0.1 ml) and stored in ice. The supernatants were applied to silica plates and eluted with solvent system 1. Authentic standards were visualised with ninhydrin, the plates divided into bands (0.5 cm) and the silica scraped into scintillation vials. Water (2.0 ml) and an aliquot (5 ml) of a solution of butyl-PBD (7.5 g) in toluene (666 ml) and Triton X-100 (333 ml) were added and the vials shaken to form a stiff gel. Radioactivity was determined using a Packard 2450 scintillation spectrometer. The histograms represent the distribution of radioactivity (c.p.m.) on the plates with reference to the R_f values of authentic standards: 1, Met^5-enkephalin; 2, H-Gly-Gly-Phe-Met-OH.

Initial studies were carried out at 37 °C with ^{3}H-Gly^3– Met^5-enkephalin (0.3×10^{-6} M) in an incubation mixture consisting of rat plasma (20% v/v) in 50 mM Tris–HCl (*p*H 7.4). These showed a breakdown pattern for the pentapeptide which is represented by the histograms in Fig. 1. At this concentration, the disappearance of Met^5-enkephalin was rapid, which is consistent with the rapid deactivation of the peptide in rat plasma. Continuation of the incubation resulted in the recovery of essentially all radioactivity as ^{3}H-glycine, indicating complete degradation of the peptide under these conditions. The main product (A), which was somewhat more stable than the parent pentapeptide, appeared to be chromatographically similar to the tetrapeptide H-Gly–Gly–Phe–Met–OH (all possible Gly^3-containing peptides were used as chromatographic standards). Product A was isolated from a larger scale incubation by chromatography on DEAE–Sephadex and purified by preparative thin layer chromatography on silica plates. After acid hydrolysis, the amino acid composition was determined and found to be compatible with the structure H–Gly–Gly–Phe–Met–OH (glycine 1.83, phenylalanine 1.17, methionine 0.85); no tyrosine was detected. The metabolite proved to be chromatographically identical to the synthetic tetrapeptide on silica plates using the solvent systems above. On the basis of this evidence, the primary step in the breakdown of Met^5-enkephalin in rat plasma is assigned as cleavage of the Tyr–Gly amide bond. As the tetrapeptide H–Gly–Gly–Phe–Met–OH shows very little activity using the mouse vas deferens assay procedure (Table 1), this cleavage is consistent with the deactivation of Met^5-enkephalin in rat plasma.

Table 1 The depressant effects of the enkephalins and degradation products on the electrically induced contractions of the mouse vas deferens

Structure	Relative activity* mouse vas deferens	$t_{\frac{1}{2}}$(rat plasma)‡ (min)
H–Tyr–Gly–Gly–Phe–Met–OH	100	2.0
H–Tyr–Gly–Gly–Phe–Leu–OH	170	2.5
H–Gly–Gly–Phe–Met–OH	0.1	–
H–Gly–Gly–Phe–Leu–OH	0.1	–

*Determined by the method of Henderson *et al.*[8].

‡Rat plasma containing the test compound (100 μg ml^{-1}) was incubated at 37 °C. Samples (0.1 ml) were taken periodically and added to 0.01M hydrochloric acid (0.1 ml). Each sample was diluted (×10) with Krebs solution and aliquots (0.1–0.3 ml) of the resulting solution injected into an organ bath (4 ml) containing the vas deferens. The depression in twitch height obtained with each sample was compared to a dose–response curve constructed for authentic methionine-enkephalin and the half life of biological activity determined.

Experiments carried out using human plasma showed that an essentially identical pattern of breakdown was taking place, though the rate of cleavage seemed to be somewhat slower.

Incubation of ^{3}H-Tyr–Leu^5-enkephalin with rat and human plasma in similar conditions resulted in the formation of a single radiolabelled product which was stable to further incubation. The R_f value of this product corresponded closely with that of tyrosine in the above thin-layer chromatographic systems, and when the product was applied to an amino acid analyser the radioactivity was eluted concurrently with authentic tyrosine. At no time was any radioactive product present which had chromatographic properties similar to any of the possible tyrosine-containing degradation products, authentic samples of which were used as chromatographic standards. This is consistent with ^{3}H-tyrosine being the primary labelled product of the degradation of ^{3}H-Tyr-Leu^5-enkephalin. Thus it seems that Leu^5-enkephalin is degraded in rat and human plasma in an identical way to Met^5-enkephalin, that is, by cleavage of the Tyr–Gly amide bond.

Breakdown of the enkephalins takes place very rapidly in the presence of rat brain homogenates: ^{3}H-Tyr–Leu^5-enkephalin (10^{-7} M) was completely destroyed within 1 min at 37 °C in a homogenate of whole rat brain containing approximately 3 mg protein ml^{-1}. The mode of deactivation seemed to be identical to that observed in plasma for both enkephalins. The subcellular localisation of the enzyme(s) responsible for the cleavage of the Tyr–Gly bond is under investigation.

The observation that the enkephalins are subject to rapid deactivation mediated by cleavage of the Tyr–Gly bond in both plasma and brain is compatible with the observed properties of the peptides *in vivo*[6,7]. It has been reported that the addition of bacitracin (a polypeptide antibiotic which has been shown to be a potent glucagon inactivation inhibitor[10]) enhances enkephalin-mediated effects on cyclic GMP accumulation in slices of rat neostriatum[9]. This enhancement may well be due to inhibition of peptidase activity by the antibiotic. It is interesting to note that, despite the lability of the peptides in brain homogenates, several groups of workers have been able to demonstrate the affinity of the enkephalins or related peptides for the opiate receptor in brain[3,4,11,12].

The important observation[7,12] that porcine β-lipotropin C-fragment (a 31-residue peptide isolated from pig pituitary which has the Met^5-enkephalin sequence at its N terminus[13]) shows potent and long lasting morphine-like effects in the cat is surprising in view of its structural relationship to the enkephalins. It is possible, however, that the tertiary structure of the longer peptide is such that the labile Tyr–Gly bond is protected from the metabolising enzyme, thus conferring greater stability on the molecule *in vivo*.

In conclusion, the deactivation of the enkephalins in rat and human plasma and in rat whole brain homogenate has been shown to take place through cleavage of the Tyr–Gly amide bond. The localisation, nature and specificity of the enzyme system responsible for the cleavage is unknown but its precise role and mode of action may be expected to have a major effect on the pharmacology and biochemistry of the enkephalins and related compounds.

Since this paper was submitted, further evidence that cleavage of the Tyr–Gly amide bond is the initial deactivation step of the enkephalins *in vivo* has been provided by structure–activity studies on enkephalin analogues. In particular D-Ala^2-Met^5-enkephalin is extremely resistant to plasma enzymes. This superactive analogue (5×Met^5-enkephalin potency in the mouse vas deferens assay) has a $t_{\frac{1}{2}}$ of at least 20× Met^5-enkephalin in rat plasma indicating the importance of the Tyr–Gly region of the molecule to the substrate specificity of the degrading enzyme(s). Similar results have been reported by other workers[14].

We wish to thank Dr J. D. Bower, Mrs C. Calverley, Mr P. Coffin, Mr R. Pape, Mr J. D. Robinson and Mr A. Wilson for their technical assistance.

Substance P and analgesia

SUBSTANCE P (SP)[1] has long been known to have marked effects on the central nervous system (CNS). Lembeck[2] suggested that SP might be a transmitter of primary sensory impulses, an hypothesis supported by subsequent investigators[3,4]. Early work on SP was carried out using natural material, which unless highly purified, is known to be contaminated with bradykin or some other kinin-like material[5]. As bradykinin also has marked effects on the CNS, experiments carried out using impure SP may be misleading. This may account for some of the conflicting observations that exist regarding the action of SP on sensory transmission, and may also explain its interaction with opioids. Whereas impure SP has been shown to antagonise morphine[6], synthetic SP was found to substitute effectively for morphine in mice chronically treated with morphine[7]. SP does not act like morphine in the field-stimulated guinea pig ileum[8] and does not combine with morphine receptors[9]. Furthermore, SP has been reported to be the most potent algogenic substance known on the human blister base[10]. Recent reports on the characterisation and activity of enkephalin[11,12] suggested that enkephalin may be acting as an analogue of SP. We have therefore examined SP for morphine-like activity.

This hypothesis was tested initially by examination of the effects of intracerebral injection[13] of SP and morphine into 30-g male Swiss Webster mice. Response of the animals to heat stimuli was tested using a hot plate analgesiometer[14]. Each mouse's reaction time (RT; s) was determined before administration of any drug and again at 30-min intervals after drug injection. Naloxone and morphine were administered in physiological saline; SP was administered in physiological saline containing 0.01 N acetic acid, to prevent adsorption of SP to glass. When used, naloxone was injected intraperitoneally immediately before intracerebral injection of other drugs. Vehicle controls were carried out. The pre-drug RT was subtracted from each of the RTs observed after treatment, and these differences in RT are reported in Table 1.

SP and morphine each caused an increase in RT, indicating analgesia; and the analgesic action of each was prevented by naloxone Mice which received SP seemed to be quiet compared with normal mice. They would cease movement, seeming to sleep, often in an abnormal posture. These animals were readily aroused, and seemed to be alert, however, while being handled and while on the analgesiometer. These behavioural effects of SP were similar to those described previously[15].

Table 1 Analgesic action of intracerebrally administered SP and morphine sulphate (MS)

Treatment	Increase in RT at: 30 min	60 min	90 min
SP (7)	3.0±0.83	5.23±0.72	8.23±1.09
SP vehicle (7)	−0.11±1.57	1.43±1.28	2.03±1.53
MS (7)	8 03±1.75	4.86±1.46	2.49±0.61
Saline (7)	−1.14±0 51	−0 41±1.16	0.63±0 6
SP+naloxone i.p. (7)	−0.54±0.23	1.11±0.48	2.97±0.52
SP+SP vehicle i.p. (7)	3.6±1.32	4.77±1.85	7.23±1.44
MS+naloxone i.p (5)	0.0±0.93	1.84±1.15	4 52±1.92
MS+saline i.p. (5)	8.69±4.50	7.32±3.97*	5.80±2.76*
Naloxone i.p.+SP vehicle i.c. (7)	−0.74±1.06*	−0.31±0.67*	
Saline i.p.+SP vehicle (7)	−0.23±0.84*	−0.31±0.88*	
Chronic MS i.p.+SP (7)	0.37±0.92	−0.26±0.72	1 51±0.66
Chronic MS i.p.+MS (5)	−0.92±1.41	1.72±1 39	0.32±1.48
Chronic saline i.p.+ SP (5)	3.77±1.70	7.50±2.11	7.90±1.83

Injections were in 0.04 ml intracerebrally (i.c.) and 0.1 ml intraperitoneally (i.p.). Doses (per mouse): SP 2 ng; MS 0 4 μg; naloxone 60 ng (i.p.). All increases in RT were statistically significant with respect to the corresponding controls using Student's *t* test ($P<0\ 05$) except those marked with an asterisk.

Number of animals per group is given in parentheses. All drug injections were made at 1030.

Table 2 Analgesic action of intraperitoneally administered SP

Time of testing (min)	Increase in RT (s) Group 1	Group 2	Group 3
30	7.04±1.91	7 6±2.69	0.3±1.48
60	6.56±2.4	11.44±3.49	2.08±1.48
90	8.36±3.2	10.96±1.33	1.12±1.41
120	6.24±1.4	8.2±3.18	3.0±0.86
150	3.84±2.12	4.08±1 26	2.32±1.20

Each group contained 5 mice, each weighing 30 g. Injections (0.1 ml intraperitoneally) were: group 1, SP 5 ng per mouse; group 2, SP 1 μg per mouse, group 3, SP vehicle alone. For other details of testing, see text and Table 1. Increased RTs of animals in groups 1 and 2 were all significant compared with group 3 ($P<0.05$) except at 150 min.

To determine whether animals made tolerant to morphine also showed cross tolerance to the analgesic action of SP, animals were given morphine chronically before testing. On the first day of this experiment the RT of each mouse was tested on the analgesiometer before drug or placebo administration. Mice were then divided into three groups. Groups 1 and 2 received three injections of morphine intraperitoneally (0.25 mg per mouse per injection) on day 1, three injections on day 2 (0.5 mg) and three injections on day 3 (1 0 mg). On day 4 mice of group 1 were given SP intracerebrally and the mice of group 2 were given morphine intracerebrally. Animals of group 3 were given saline injections on days 1, 2, and 3, and received SP on day 4. The last part of Table 1 shows that mice treated chronically with morphine did not show any analgesic reaction to morphine or SP, whereas mice given chronic saline responded normally to SP.

Since SP has been reported to cross the blood–brain barrier[7], it was also tested for analgesic action after peripheral administration. The experimental protocol was similar to that of the initial experiment described above, except that SP was administered by intraperitoneal injection Table 2 shows that SP caused significant analgesia in mice at dose levels of 5 ng or 1 μg per mouse At all times except 150 min, the changes in RT of animals in groups 1 and 2 were statistically significant compared with vehicle controls (group 3). The changes in RT at 150 min were not statistically significant, probably because of the small number of animals used and the fact that the analgesia was wearing off at that time.

In view of these results, the reported algogenic action of SP on the human blister base was re-examined using synthetic SP Blisters were raised on the volar surface of human forearms by application of Cantharone (0.7% canthardin in collodion). After 20 h the blister top was removed and the fibrin layer removed from the base. Substances to be tested were dissolved in buffered physiological saline and applied to the blister base[10]. Synthetic SP was not algogenic at concentrations up to 1 mg ml^{-1}, whereas acetylcholine and bradykinin were potent algogens. Algogenicity of acetylcholine and bradykinin was not antagonised by SP or Leu^5-enkephalin. The previously-reported[10] algogenicity of SP on the blister base may have been attributable to kinin contamination, since the SP used was isolated material. The failure of SP to produce analgesia on the blister base suggests that its site of action is central, as is that of morphine. The interaction we observed between SP, morphine and naloxone also supports this postulate.

We have found SP to be a potent analgesic in mice. This action of SP *in vivo* is in sharp contrast to the reported failure of SP to act like morphine on the field-stimulated guinea pig ileum[8] or in binding to morphine receptors[9]. Since SP is a powerful stimulant for contraction of the ileum, it is possible that this latter activity may have obscured any morphine-like inhibition of contraction. With respect to receptor binding, it is possible that more than one type of morphine receptor exists in CNS tissue and that the one tested by Terenius[9] may not combine with SP. The SP receptor may possibly be degraded during the isolation procedure. It is possible that the analgesic action of SP may be mediated through the release of other substances. Another possibility is that the analgesia after administration of SP is not attributable to the intact molecule, but a metabolite of it. The slow onset and prolonged duration of action of SP compared with morphine may lend support to this hypothesis. Arguing against this possibility is the observation of Otsuka *et al.*[4], who found that shorter C-terminal fragments of SP, which retain relatively high myotropic potency, had little depolarising activity in frog spinal motoneurones.

It has been reported that enkephalin, which comprises residues 61–65 of β lipotropin, has only very transient and probably insignificant analgesic action *in vivo*[16], whereas the much larger C-fragment (residues 61–91 of β lipotropin) is an active, potent, *in vivo* analgesic[17]; these data were obtained by intracerebral injection of the peptides. Our finding of the potent analgesic action of SP after peripheral administration suggests that the development of a small peptide as a practical analgesic drug may be possible. The intraperitoneal route of administration should minimise any undesirable hypotensive effects of SP, and its already prolonged analgesic action may be further prolonged by depot forms of administration.

Colchicine inhibits mitogenesis in C1300 neuroblastoma cells that have been arrested in G_0

CELLS in G_1 or G_0 usually progress through the cell cycle and stop in metaphase when colchicine is added to the growth medium[1–6]. I have observed, however, using two different experimental techniques, that mouse C1300 neuroblastoma cells reversibly arrested in G_0 by serum limitation[7] are unable to re-enter the cell cycle in the presence of colchicine.

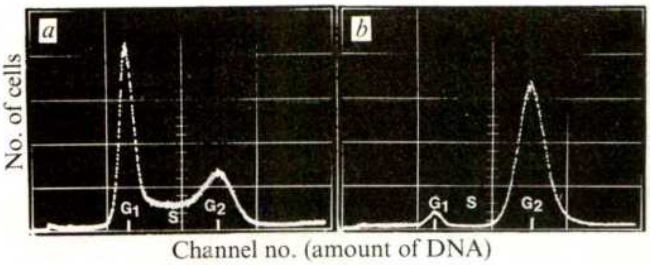

Fig. 1 Effect of colchicine on exponentially growing C1300 neuroblastoma cells. FMF analysis (*a*) before colchicine and (*b*) 40 h after addition of 1 μg ml^{-1} colchicine to the growth medium. C1300 cells were treated as described by Crissman and Tobey[11] to obtain a monodisperse suspension. Cells were stained with mithramycin and passed through a Los Alamos design microfluorometer[10] equipped with an argon laser excited at 457 nm. The fluorescent light flash from each cell, which is proportional to the cell's DNA content, was converted to an electrical pulse by a photomultiplier and stored in a multichannel pulse-height analyser. The data were also displayed on an oscilloscope as shown above.

Colchicine inhibited by about 85% the incorporation of ^{3}H-thymidine into DNA from 21 to 28 h after the arrested C1300 cells were returned to complete growth medium (Table 1). This could mean that C1300 cells do not leave G_0, or progress more slowly through the cell cycle, or do not take up thymidine[8]. A second technique, flow microfluorometric (FMF) analysis[9–11], which can determine the distribution in the cell cycle of a cell population by measuring the DNA content of individual cells, was used to distinguish among these possibilities. FMF analysis showed that after 44 h in growth medium plus colchicine about 85% of the original cell number is still in G_0 (Table 1). Colchicine therefore prevents C1300 cells from leaving G_0. The effect of colchicine additions at 10, 17, and 20 h after the cells were returned to DEM+10% calf serum (Table 2) suggests that the block involves the latter part of G_0 but not S phase. Colchicine inhibits mitogenesis in C1300 cells in G_0 but not

*C1300 cells, which were arrested in G_0 by serum limitation[7], were plated in Dulbecco's modified Eagle's medium (DEM)+10% calf serum at 2.5 × 10^5 cells per 60-mm Petri dish (Falcon). Colchicine was added about 30 min later. Cultures were pulsed with 5 μCi ^{3}H-thymidine in 0.10 ml 1.5 × 10^{-4}M non-radioactive thymidine from 21 to 28 h after plating. Cells were collected on glass-fibre filter papers, washed twice with Tris-saline buffer, twice with 10% TCA and once with 95% ethanol. The filter papers were counted in a scintillation fluid containing 4.2% Liquifluor in a liquid scintillation counter. Each sample point was done in duplicate. The variation between points was less than 10%. These results are from one of several experiments, all of which showed this effect. The sample without colchicine added had 70,000 c.p.m.

Cells were monitored for their ability to maintain a healthy clumped morphology in the suspension culture and to exclude Trypan blue. At all colchicine concentrations, for the first 30 h of the experiment, the cells grew in healthy clumps in suspension and over 90% excluded Trypan blue. By 48 h, however cultures with 1 μg ml^{-1} colchicine had smaller clumps and only 75% of the population excluded Trypan blue. The cells appeared to deteriorate after 45 to 50 h at this colchicine concentration. At the lower colchicine concentrations, the cells appeared clumped and at least 85% excluded Trypan blue after 48 h.

†FMF analysis in parallel cultures to the first part of the experiment was carried out as described previously[7,9–11] using the mithramycin staining procedure[11]. FMF experiments carried out parallel with other ^{3}H-thymidine incorporation experiments gave similar results.

*Results for colchicine concentration of 1 μg ml^{-1}. Similar results were observed at colchicine concentrations of 0.5 and 0.1 μg ml^{-1}.

†TCA-precipitable ^{3}H-thymidine incorporation was measured 21 to 28 h after the arrested cells were returned to DEM+10% calf serum. Assay was carried out as described in Table 1 and ref. 7. In addition, FMF analysis was carried out on parallel cultures 48 h after the cells were returned to DEM+10% calf serum.

in G_1, since only 5% of an exponentially-growing cell population is in G_1 (Fig. 1) 40 h after addition of 1 μg ml^{-1} colchicine to the growth medium. Vinblastine sulphate (1 μg ml^{-1}) also inhibits the re-entry into the cell cycle of C1300 cells arrested in G_0.

The mechanisms of growth regulation in normal and transformed cells are still being elucidated[6,7,12,13]. The cell membrane is thought to have a central role in controlling cell growth, in part by mediating the effects of serum factors that signal a cell to proliferate early in G_1 or G_0 (refs 14–17). This concept and the evidence that colchicine and other microtubule-disrupting drugs can affect the topographical distribution of receptors in the cell membrane[18–23] could explain my results. Colchicine may be altering the topographical distribution of receptor(s) for serum factor(s) required by the arrested C1300 cells to re-enter the cell cycle.

The results presented in Table 2 show that C1300 cells can receive a 'stop' signal late in G_0, some considerable time after the initial 'go' signal is received from serum factors[17]. This suggests that the mechanism of mitogenesis depends on specific receptor configuration(s) in late G_0 as well as in early G_1 or G_0 (refs 15–17).

Combinations of drugs that include a microtubule-disrupting agent are more effective than single drugs in treating tumours[24,25]. The results presented here suggest that this may be due, in part, to the effect the microtubule disrupting agent has on cells in G_0. The development of selective approaches to alter the mobility of receptors on the plasma membrane may prove useful in controlling malignant cell growth.

Gunther *et al.*[26] have shown that colchicine inhibits mitogenesis in lymphocytes. Also, colchicine inhibits mitogenesis in mouse 3T3 cells and dog MDCK kidney cells that have been reversibly arrested in G_0 (M. Baker, unpublished).

I thank Drs H. Friedman, R. W. Holley, J. Lockwood, G. Sato, J. Schneider, S. Varon, and the Human Biochemical Genetics Program, USPHS, for facilities and/or supplies. During part of this study, I was supported by a Senior Dernham Fellowship from the California Division of the American Cancer Society. I also thank Dr R. W. Holley for additional financial support (USPHS grant from the NCI) and encouragement; G. Baker, P. Schwalbe, and M. F. Weissberg for financial assistance; and Nathan Belcher, Pfizer Inc., for mithramycin.

Inhibitory action of glutamic acid on cerebellar interneurones

GLUTAMIC acid strongly excites almost all central neurones examined, and it has been considered to be a main excitatory transmitter in the mammalian brain[1,2]. Although some neurones in the olfactory bulb have been inhibited by glutamic acid[3], this has been explained by the assumption that glutamate primarily activated γ-aminobutyrate (GABA)-releasing inhibitory interneurones, which in turn inhibited the neurones in question[1]. In the experiments reported here, glutamate inhibited neurones in the granular layer of the cerebellum: this action does not seem to be mediated by inhibitory interneurones.

Thin sections of guinea pig cerebellum (80–120 μm thick) were prepared from the uvula and nodulus perpendicular to the long axis of the folium as before[4]. They were incubated in glucose–saline medium saturated with 95% O_2 and 5% CO_2 at 37 °C for more than 40 min, and transferred one by one into an observation chamber under a microscope[5]. Single cell discharges were recorded extracellularly from neurones in the granular layer with glass microelectrodes of tip diameter 2–4 μm.

About half the neurones encountered in the granular layer were excited by glutamate (GE cells) and others were inhibited (GI cells) (Fig. 1). When glutamate was administered electrophoretically to a point about 30 μm from the tip of the recording pipette, the discharge rate of a GE cell started to increase within 1 s (Fig. 1*b*). The rate of firing of a GI cell, on the other hand, gradually decreased and then stopped (Fig. 1*a*, 1). Firing resumed after the electrophoretic current was turned off. An increase in electrophoretic current shortened the latency of inhibition (Fig 1*a*, 2). In some GI cells, contact of a pipette containing glutamate with the section near the recording site induced suppression of the firing even if a retaining current of 25 nA was passed continuously through the pipette (Fig. 2*a*, 1). This was probably due to a background leakage of glutamate which was reported to occur occasionally in spite of the retaining current[5]. In these cells, reduction of the retaining current caused stronger inhibition, and reversal of the current further increased the inhibition. Therefore, the inhibition observed during administration of glutamate cannot be explained by the electrotonic effect of current flow. This conclusion is strengthened by the observation that the neurones identified as the GI cells by electrophoretic administration of glutamate were also inhibited consistently when the sections were perfused with medium containing 0.1–0.3 mM glutamate.

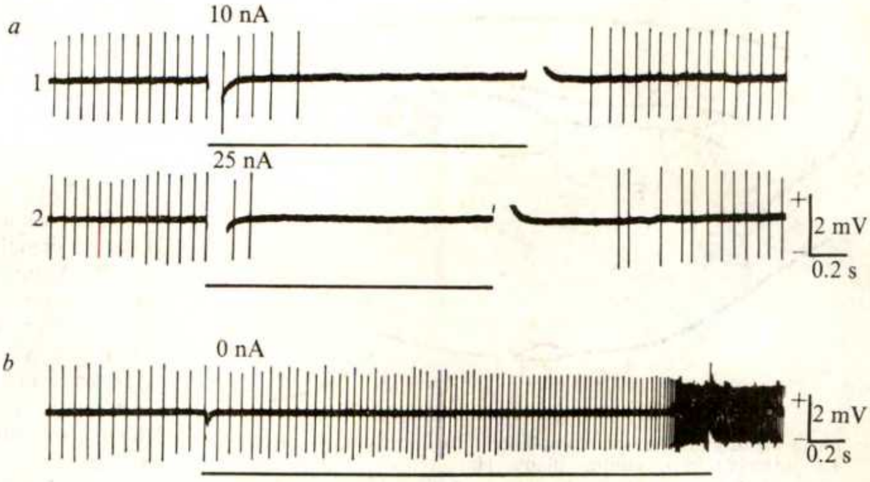

Fig. 1 Responses of cerebellar interneurones to glutamic acid administered to nearby points. *a*, Recorded from a GI cell. Electrophoretic currents were administered during the periods indicated by the solid lines beneath the records. Intensities of the currents are shown above the records. *b*, Recorded from a GE cell. Solid line: the retaining current of 25 nA was turned off.

The firing of the GI cells was suppressed not only by glutamate but also by GABA. In the experiment illustrated in Fig. 2, the extension of the area in which GABA administration effectively suppressed the firing of a GI cell (GABA-sensitive area) was compared with the extension of the glutamate-sensitive area defined similarly. If GABA inhibits a GI cell directly and glutamate works through mediation of inhibitory interneurones, it would be expected that the extension of the GABA-sensitive area would not coincide with that of the glutamate-sensitive area. In all six GI cells studied, however, both areas almost agreed with each other (Fig. 2). Inhibition by glutamate was not blocked by strychnine (0.5 mg l^{-1}) or pictrotoxin (50 mg l^{-1}), the latter being found to block the action of GABA. Although inhibition by GABA was blocked in the medium in which Cl^- was substituted by propionate ions, inhibition by glutamate was not affected in Cl-free medium. Thus inhibition by glutamate is not mediated by GABA-releasing neurones. Moreover, inhibition by glutamate was maintained in the medium containing 16 mM Mg^{2+}, in which synaptic transmission in brain slices was reported to be completely blocked[6]. This result excludes the possibility that interneurones intervene in the inhibition by glutamate.

In the cerebellar sections used in these experiments, individual neurones in the granular layer were not distinctly visible under a microscope. Therefore, the GI cells have not been identified morphologically. At least some of the GI as well as GE cells, however, seem to be large Golgi cells, because action potentials exceeding 5 mV in amplitude were sometimes recorded from the GE and GI cells with electrodes of relatively large tips. When an electric shock was applied to the white matter, the GI cells were inhibited and the GE cells were activated. This suggests that the distinction between the GE and GI cells is not only of pharmacological but also of physiological significance.

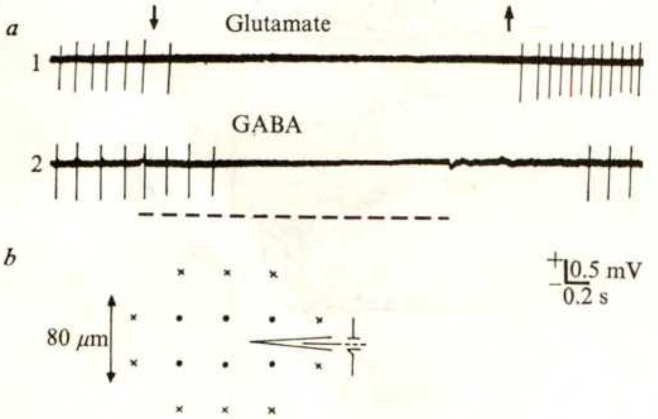

Fig. 2 Suppression of firing of a GI cell by glutamic acid and GABA. *a*: 1, the tip of a pipette filled with 1 M sodium L-glutamate, *p*H 8.2, touched a point indicated by dots in (*b*) approximately at the time marked by an arrow pointing downwards. The approximate time at which the pipette was removed is marked by an arrow pointing upwards. The retaining current of 25 nA was passed continuously through the pipette. 2, GABA was administered to the same point with an electrophoretic current of 25 nA during the period indicated by a broken line. *b*, Glutamate and GABA inhibited the cell when administered to the points indicated by dots but had no effect when administered to the points indicated by crosses.

Growth of transplanted monoaminergic neurones into the adult hippocampus along the perforant path

CENTRAL and peripheral monoaminergic neurones have been found to survive transplantation to certain sites in the adult rat brain[1]. The neurones grow extensively in their new location and the newly formed axons extend through the surrounding scar tissue into the host brain. We now report experiments in which transplants of adrenergic, dopaminergic or indolaminergic neurones were transplanted to a cavity in the retrosplenial cortex to give them the opportunity to grow along the lesioned temporoammonic perforant path into the partly denervated hippocampal formation. The results demonstrate a remarkable ability of the regenerating axons to establish reproducible and characteristic terminal patterns in large areas of the hippocampus.

As described previously[1], transplantation involved the placement of pieces of embryonic brainstem—containing major noradrenaline (NA), dopamine (DA), or indolamine (IA) cell groups—or a piece of a mature sympathetic ganglion in a resection cavity in the occipital pole[1], in contact with or in proximity to the dorsal hippocampus (Fig. 1). The operation involved a major portion of the perforant path fibres innervating the dorsal part of the hippocampal complex[2–5]. Four types of material were transplanted: (1) a half to a third of the superior cervical

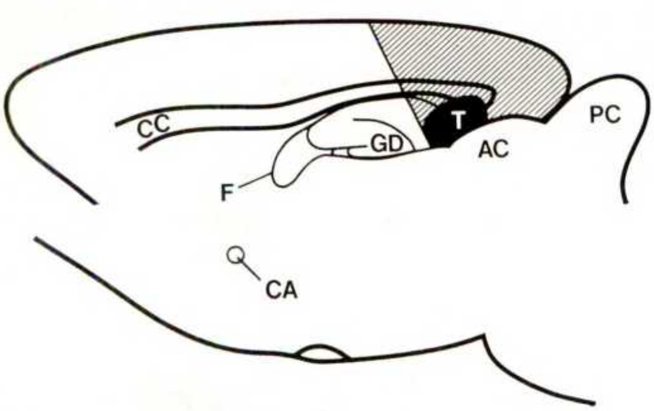

Fig. 1 Position of the neural implants in the hippocampal region, as illustrated in a sagittal plane. Hatched area denotes the extent of the resection cavity. The transplant (T) was placed, under visual control, on to the richly vascularised pia covering the underlying colliculi. The lesion involved part of the entorhinal, retrosplenial and occipital cortex, and the dorsal part of the subicular complex. All animals were subjected to complete intracranial sympathectomy before or at the time of transplantation. AC, Anterior colliculus; CA, anterior commissure; CC, corpus callosum; F, hippocampal fimbria; GD, dentate gyrus; PC, posterior colliculus.

ganglion taken from the adult recipient rat (autologous transplantation); (2) the ventromedial mesencephalon taken from embryos, containing primarily DA neurones; (3) the locus coeruleus region of the pons, taken from embryos, containing primarily NA neurones; (4) the pontine raphe region, taken from embryos, containing primarily IA neurones. These pieces of central nervous system (CNS) were dissected from embryos with a crown–rump length of 15–25 mm, essentially as described by Olson and Seiger[8], and they were transplanted homologously into adult rats (Sprague–Dawley; 180–200 g body weight).

The animals were killed 1–6 months later. To remove the normal monoaminergic innervations of the hippocampal formation, about half the recipients were given an intraventricular injection of either 6-hydroxydopamine (6-OHDA; 250 μg) or 5,7-dihydroxytryptamine (5,7-DHT; 150 μg) 2–6 d before transplantation. Brains were processed for fluorescence histochemistry according to the Falck–Hillarp formaldehyde method (for technical details, see ref. 7). Animals bearing IA transplants were treated with the monoamine oxidase inhibitor nialamide (300 mg $\mathrm{kg^{-1}}$) 3–5 h before killing, to facilitate visualisation of fibres containing 5-hydroxytryptamine (5-HT).

There were up to about 200 surviving, fluorescent neurones in the peripheral NA transplants, and up to about 500 in the central NA, DA and IA transplants (see ref. 1 for further details of fluorescence microscopical features of the transplants). Of the 18 ganglionic transplants studied, all survived except one, and 26 of the 33 CNS transplants survived. Abundant fibre outgrowth was demonstrable from all four types of transplant. In 19 out of the 26 surviving CNS transplants and in 16 of 17 surviving ganglionic transplants the outgrowing fibres grew into the hippocampal formation, above all the dentate gyrus. The transplantation lesion involved the dorsal presubiculum and subiculum, and a minor adjoining portion of CA 1. In some cases there was also a minor lesion in the dentate gyrus (Fig. 2*a* and *b*). Consequently, the outgrowing nerve fibres grew towards a largely intact dentate gyrus and towards the cut surface of CA 1, as shown semischematically in Fig. 2. There was an obvious preferential orientation of the newly formed fibres towards the dentate gyrus; this was most clearly demonstrated when the transplant was placed some distance from the dentate, as in Fig. 2*a* and *c*. In such cases the fibres had grown through the surrounding scar tissue for up to

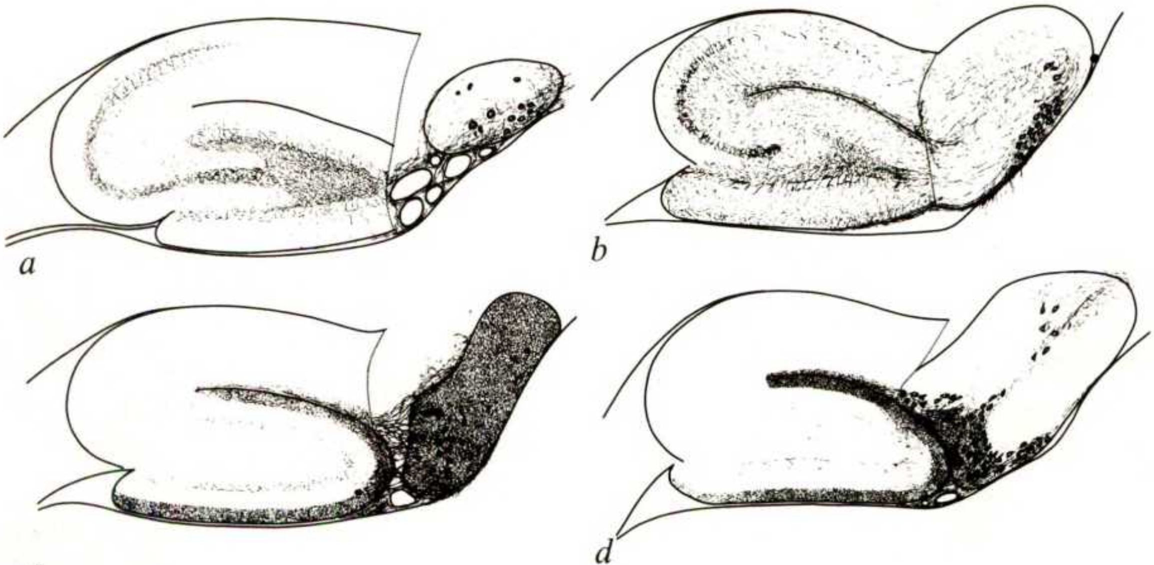

Fig. 2 *a–d*, Semischematic drawings, in the sagittal plane, of the fibre outgrowth from four types of neural transplants towards the hippocampus (compare Fig. 1). *a*, Superior cervical ganglion, 6 months survival. The recipient rat was given 250 μg 6-OHDA, intraventricularly, 2 d before transplantation. The transplant, which underwent considerable atrophy, contained about 90 ganglionic nerve cells with a fairly normal and healthy fluorescence microscopical appearance. This animal had also a minor lesion of the fimbria, which probably caused some increase in the fibre ingrowth. *b*, NA transplant taken from an embryo with a crown-rump length of 25 mm, 3 months survival. The normal adrenergic and indolaminergic innervations of the hippocampus had been removed with an intraventricular injection of 150 μg of 5,7-DHT, 6 d before transplantation. The transplant, which retained approximately its original size, contained about 450 surviving catecholamine-containing neurones confined to two major cell clusters. *c*, IA transplant taken from an embryo with a crown-rump length of 15 mm, 3 months survival. The transplant was filled with a dense pattern of newly formed IA fibres. Because they obscured many of the surviving IA cell bodies it was not possible to assess their number. *d*, DA transplant from an embryo with a crown-rump length of 20 mm, 6 weeks survival. The normal hippocampal adrenergic and indolaminergic innervations had been removed by a 5,7-DHT injection 3 d before transplantation. The transplant, which probably had increased somewhat in size, contained several hundred surviving fluorescent catecholamine neurones, intermingled with a dense plexus of locally ramifying DA fibres.

1–1.5 mm in rostral, lateral and ventrolateral directions to reach the adjacent dorsal part of the hippocampus and the dentate gyrus. In those specimens where the fibres had failed to reach the hippocampus the transplant had either been displaced more than 1–1.5 mm away from the dentate gyrus, or (in the case of CNS tissue) the surviving monoamine neurones were separated from the dentate by 1 mm or more of transplanted tissue devoid of monoamine neurones.

The fibres grew into the dentate gyrus either along the shortest course straight into the dentate, or along the hippocampal fissure into the dentate gyrus and the hippocampal CA 1 and CA 3 regions. In some cases the fibres also passed for some distance along the pia of the ventral surface of the dentate gyrus before entering the underlying tissue. Although the amount of fibres that grew into the hippocampal formation from the transplant varied from specimen to specimen, their patterning was remarkably reproducible and showed distinct and consistent differences among the several types of grafted neurones.

The peripheral NA neurones had formed a dense varicose terminal pattern in the hilar region as illustrated in Fig. 2*a* for a specimen taken 6 months after transplantation. Only a few fibres had passed through the granular layer into the basal part of the molecular layer. The outer part of the molecular layer was consistently devoid of fibres. Growth into the hippocampus proper was much more sparse. The fibres appeared to reach the CA 3 region from the dentate gyrus, and in most specimens fibres occurred only in the part of CA 3 close to the dentate. In the 6-month specimen (Fig. 2*a*) the ganglionic fibres had grown through CA 3 into part of the CA 1 region. The patterning of the ganglionic fibres was remarkably similar to that of the normal adrenergic nerve supply (Fig. 3*a*, compare refs 8 and 9). These fibres were identified as coming from the transplant by observations with recipients in which the normal adrenergic innervation of the hippocampal formation had been removed by pretreatment with 6-OHDA. The completeness of the denervation was checked in the contralateral hippocampus.

The growth of fibres from the transplanted central NA neurones was studied in rats pretreated with 5,7-DHT. This removed both the normal NA and 5-HT innervations of the hippocampal complex, and the denervation persisted for at least 6 months (Fig. 3*b*). Within 1–3 months of transplantation the dorsal part of the dentate gyrus and, in some specimens, the hippocampal CA 3 and CA 1 regions received a new fluorescent fibre supply that could be traced back to the NA transplant (Fig. 2*b*). In the dentate gyrus these fibres had—like the normal adrenergic innervation—their densest distribution in the hilar region. From here fibres could be traced through the granular layer into the molecular layer where irregularly running fibres were found throughout its width (Fig. 3*c*). In some specimens, such as the one in Fig. 2*b*, the ingrowing fibres tended to aggregate in the outer part of the molecular layer. The fibres reached CA 3 and CA 1 either from the hilus or along the hippocampal fissure. The magnitude of ingrowth into these areas varied considerably. In the richest specimens (Fig. 2*b*) the new fibre supply covered approximately the dorsal two-thirds of the hippocampus. There was a marked difference between the CA 3, which demonstrated a fairly rich fibre supply in all layers, and the CA 1, where the ingrowing fibres were only sparse and scattered.

The distribution of fibres growing from the central IA transplants (observed in both non-pretreated and in 5,7-DHT-pretreated recipients) was different from that of the central and peripheral NA fibres. The IA transplants formed a layer of densely packed varicose fibres in the outer half of the molecular layer in the dentate gyrus (Figs 2*c* and 3*d*). Occasionally, fibres were seen to have grown along the hippocampal fissure to form a similar fibre band in part of the stratum lacunosum-moleculare in CA 1 (Fig. 2*c*). The position of these fibre bands seems to conform to the normal distribution of the terminals of the perforant path fibres[4,5,10]. The fibre supply to the lower half of the molecular layer and the granular layer was much more sparse. This was the case also in the hilar region where usually the densest 5-HT innervation is found (compare ref. 11). The IA fibres were not seen to extend into CA 3.

The fibres from the central DA transplants had a characteristic delicate and fine varicose appearance (similar to that of normal central DA terminals) and they were thus well distinguishable from the normal NA innervation also seen in the non-pretreated animals. Like the IA fibres, the outgrowing DA fibres formed a dense, fine varicose fibre band in the outer half of the molecular layer in the dentate gyrus. Figure 2*d* illustrates a case with an unusually large number of surviving DA neurones, where the ingrowing fibres had covered the entire dorsal dentate. Moreover, a dense band of DA fibres had been formed also in the stratum lacunosum-moleculare of CA 1. The inner part of the dentate molecular layer occasionally had a dense supply in the portion closest to the transplant. Otherwise, only few fibres were observed in the inner part of the molecular

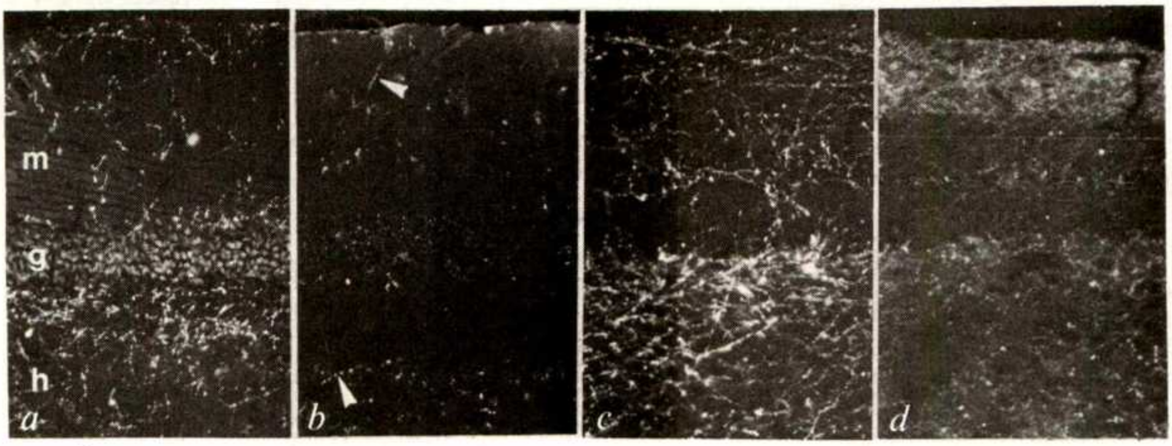

Fig. 3 Detail of the dorsal part of the dentate gyrus showing: *a*, normal adrenergic innervation in a control rat; *b*, adrenergically denervated dentate gyrus in a rat treated with 150 µg of 5,7-DHT (taken from the contralateral, control side of the transplanted rat shown in (*c*)). Only some single, scattered terminals remain (arrows). *c*, Patterning of adrenergic fibres originating from a NA transplant, 3 months survival (the dentate was adrenergically denervated before transplantation, as shown in (*b*). *d*, Patterning of indolaminergic fibres originating from an IA transplant, 3 months survival. m, Molecular layer; g, granular layer; h, hilus. Compare Fig. 2. (× 90)

layer and in the hilus, and none was found in the hippocampus proper.

The transplanted central and peripheral neurones were allowed to grow towards a hippocampus that had been partially deafferented through a lesion in the perforant path system and by removal of the monoaminergic brainstem afferents. From the transplant, located in the resection cavity in the retrosplenial cortex, the growth of the new fibres was directed along a course roughly corresponding to that of the lesioned perforant path fibres (compare refs 2–5). Entering the hippocampus through presubiculum and subiculum, the perforant path fibres are known to run through and along the hippocampal fissure to terminate heavily in the outer part of the molecular layer in the dentate gyrus. In interpreting our data, it seems that the outgrowing fibres of all different monoamine neurone types will find their way into the dentate gyrus along the degenerated perforant path, and that two of them, the IA and DA neurones, will distribute their fibres in a manner strongly resembling that of the perforant path fibres. The central and peripheral NA fibres, on the other hand, pattern themselves differently, the most heavy termination being in the hilar region, just as the normal adrenergic innervation. This growth process can be viewed as an attempt at a heterologous reinnervation of the dentate gyrus by regeneration of peripheral adrenergic neurones or by outgrowth of developing central neurones. Contrary to the traditional view that the scar tissue and the composition of the CNS tissue prevent axonal outgrowth in the adult mammalian brain[12–14], the axons of the transplanted neurones grew without any apparent obstacle up to at least 1 mm through the developing scar tissue, through the pial covering in the hippocampal fissure, and penetrated deeply into the dentate gyrus and the hippocampus. Here the newly formed fibres extended for distances of up to 3–4 mm from the transplant.

The most intriguing feature of this process is that different types of fibres, although growing along the same route, form distinctly different and highly consistent patterns in the hippocampal formation. This strongly suggests that directional and organising forces—not unlike those demonstrated in lower vertebrates[15–17]—are operating also in the brains of adult mammals. And in view of the fact that such biochemically closely related neurones as the DA and NA neurone types pattern themselves entirely differently, it seems that these mechanisms have a high degree of precision and selectivity. Nothing is known so far about the ultrastructural mode of termination of the outgrowing fibres. But on the basis of their light microscopic distribution it seems possible that the transplanted IA and DA neurones (and to some minor degree perhaps also the central NA neurones) had grown to fill the terminal space vacated by the lesion of the non-monoaminergic perforant path, and that the adrenergic neurones had regenerated a fairly normal innervation pattern. This is in line with the idea that mechanisms adequate for the re-establishment of severed fibre connections are present in the mammalian brain, but that these mechanisms are not entirely specific for the appropriate neurone type.

Progesterone may act at hypothalamus and pituitary by way of enhancement of oestrogen retention

PROGESTERONE injection given 24 h or more before ovulation inhibits the ovulatory cycle[1–5]. There is evidence that progesterone can act directly on the hypothalamus[6–9] to block ovulation and on the pituitary to reduce pituitary sensitivity to luteinising releasing hormone[10,11]. Steroid-sensitive target tissues including hypothalamus[12,13] and pituitary[14–16] contain

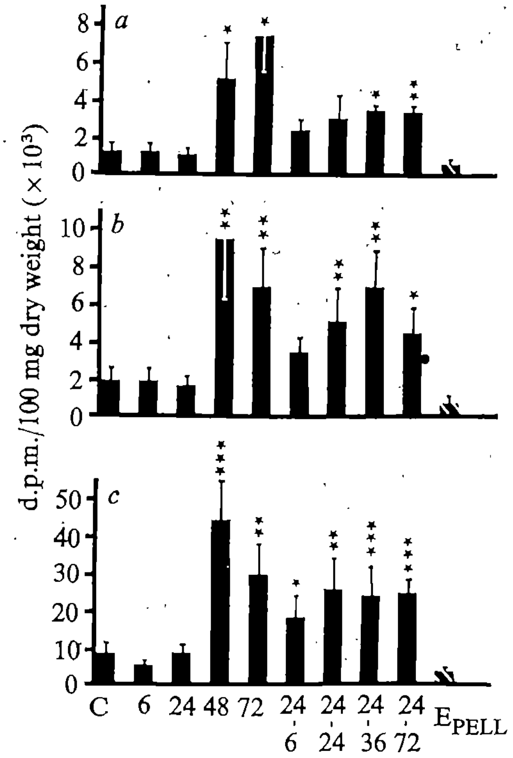

Fig. 1 Adult Sprague–Dawley rats, ovariectomised 14 d previously, received an intraperitoneal injection of 2 μCi per 100 g body weight of 2,4,6,7-^{3}H-oestrodiol (100 Ci mM^{-1}) in 0.9% NaCl. Previously the animals ($n = 10$) received a 50-mg subcutaneous pellet of progesterone for 6, 24, 48 or 72 h. Other groups had the progesterone pellet removed after 24 h and ^{3}H-oestradiol injected 6, 24, 36 or 72 h later. Saturation of the specific retention system was achieved by subcutaneous implacement of an oestradiol pellet for 72 h (E_{pell}). Two hours after ^{3}H-oestradiol injections, the animals were killed, perfused with saline and the tissues removed as described previously for hypothalamus[19]. Tissues were dried at 60 °C, weighed and then rehydrated in Tris–EDTA. After grinding in all-glass homogenisers extraction was carried out twice with 5 ml ethyl acetate. Combined extracts from a single tissue were dried in scintillation vials. The scintillation cocktail was 0.4% POP and 0.03% POPOP in toluene. Thin lines indicate s.e.m. Student's t test was used in the statistical analysis: $^*P = 0.05$; $^{**}P = 0.01$; $^{***}P = 0.001$. *a*, Preoptic–anterior hypothalamus; *b*, arcuate–median eminence; *c*, pituitary. E_{pell}, non-saturable oestrogen retention.

a specific oestrogen retention mechanism of limited capacity. Oestrogen-regulated events can be demonstrated only in the presence of a functional retention (receptor) system for oestrogen. In contrast, no specific progesterone retention system has yet been demonstrated for hypothalamus or pituitary. Does progesterone interact with these target tissues in a novel manner? This seems unlikely since other steroids which have been studied—for example, adrenal corticoids[17] and androgens[18]—have been found to bind to specific receptors in their target tissues. We therefore tested an alternate possibility that progesterone action on hypothalamus and pituitary might result in modification of the oestrogen receptor system. We tested ^{3}H-oestradiol retention by hypothalamus and pituitary after *in vivo* treatment with progesterone (subcutaneous pellet; release rate=1.5–3 mg d^{-1}) of various durations from hours to days. *In vitro* ^{3}H-oestradiol-specific retention by oestradiol–receptor complexes transferred to the nuclear fraction of these tissues was also compared for animals receiving previous *in vivo* progesterone treatment compared with ovariectomised animals not receiving progesterone treatment.

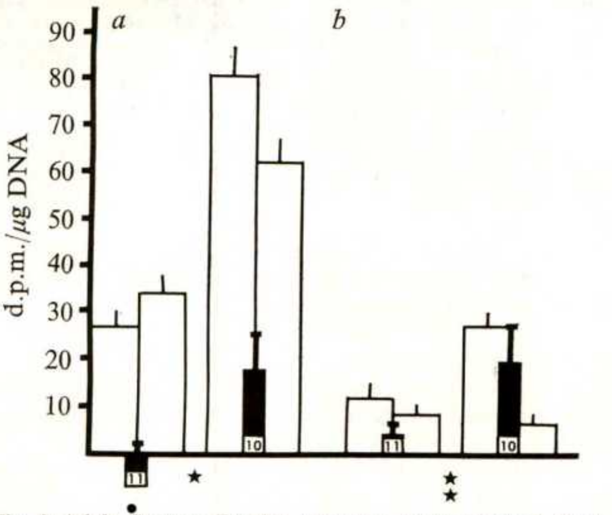

Fig. 2 Adult Sprague–Dawley rats were ovariectomised 14 d before the experiment. Half the animals (right-hand sets of columns) received a 50-mg subcutaneous pellet of progesterone on day 11. The animals were killed by exsanguination. Left-hand sets, controls. After homogenisation of the tissue (0.32 M sucrose, 3 mM $MgCl_2$, 3 mM K_2MP04, 14 mM 2 mercaptoethanol, *p*H = 6.5) one half of each homogenate was incubated at 30 °C for 1 h in 1.0×10^{-8} M 2,4,6,7-^{3}H-oestradiol. The other half was incubated in the same concentration of ^{3}H-oestradiol plus 1.0×10^{-8} M unlabelled oestradiol plus 1.0×10^{-5} M diethylstilboestral. Nuclear purification followed the methods of Løvtrup–Rein and McEwen[20] with slight modification. The nuclear fractions were extracted twice with ethyl acetate and twice with ethanol–diethyl ether (50:50) at 50 °C. Extracts were dried in scintillation vials and counted using 0.4% POP and 0.03% POPOP in toluene. DNA was extracted from the nuclear fraction and measured by the method of Kissane and Robins[21]. *a*, Hypothalamus; *b*, pituitary.

Our *in vivo* studies (Fig. 1) show that in the continued presence of progesterone a significant increase in ^{3}H-oestradiol retention has occurred by 48 h and is still expressed at 72 h. The magnitude of this increase was pituitary> arcuate–median eminence > preoptic–anterior hypothalamus. When the animals are exposed to progesterone for 24 h, no change in ^{3}H-oestradiol was observed if the progesterone source was removed at that time; a significant increase in ^{3}H-oestradiol retention was found for pituitary at 30 h, at 48 h in the arcuate–median eminence region, and at 60 h in the preoptic–anterior hypothalamic region. Thus, in the continued presence of the progesterone source, all tissues showed a response at 48 h. When the response was measured after removal of the progesterone source, however, the pituitary showed the shortest response interval (30 h). These data on *in vivo* total tissue retention are supported by the demonstration that the specific *in vitro* oestrogen retention by the nuclear fraction was significantly enhanced when ovariectomised animals were pretreated with progesterone for 72 h (Fig. 2).

Our study shows that progesterone treatment *in vivo* significantly modified oestradiol retention, studied *in vivo* for whole tissue and *in vitro* for the nuclear fraction from hypothalamus and pituitary of female rats. This supports the concept of progesterone acting both at the neural level[6–9] and pituitary[10,11] level in regulation of the ovulatory cycle. Exposure of the pituitary and the neural tissues to progesterone for 48 h resulted in an increase in specific oestradiol retention. This increase could be observed for at least 72 h after the end of 24 h progesterone treatment. The change in oestradiol retention observed after 24 h of progesterone treatment correlates with the time required for progesterone to inhibit events of the ovulatory cycle.

At present, no nuclear progesterone receptor has been demonstrated for the hypothalamus or the pituitary. Through some mechanism requiring progesterone and at least 24 h, however, the amount of oestradiol receptor found in the nuclear fraction is increased. The possibilities of whether the biological effect of progesterone on the ovulatory cycle is mediated by an increase in oestradiol receptors in these tissues, or whether the increase in oestradiol receptors is caused by a progesterone-mediated block of a later step in the oestradiol–receptor–genome interaction is under investigation.

Combination of insulin chains on an anti-insulin antibody–Sepharose column

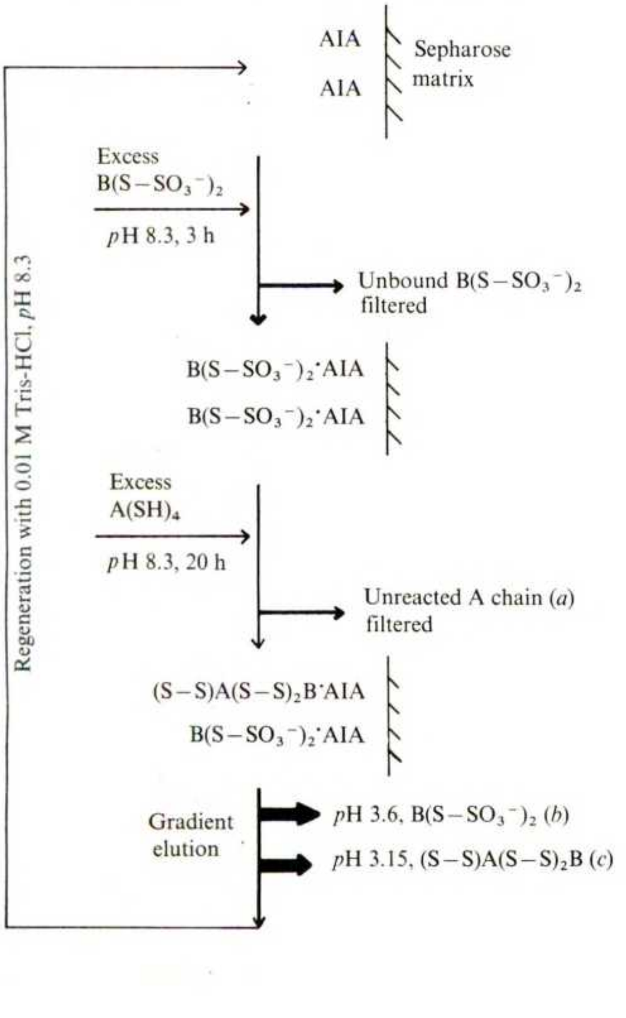
WHEN the mixture of products obtained by combining insulin A and B chains in solution (for a review, see ref. 1) was chromatographed on an anti-insulin antibody–Sepharose column[2] no clear separation was achieved[3]. From the low biological activity (24.1%) of the material with the same antibody affinity as natural insulin (10.9% of the total bound products) it was concluded[3] that resynthesised insulin with authentic structure constituted only a small portion of this fraction. Combination of insulin chains in solution has always involved a number of steps[4,5] and has produced a mixture of products from which pure active insulin could be isolated by gel filtration and ion-exchange chromatography[6]. Linking the chains using the procedure described in this report, however, has given only one combination product that, according to various criteria, was identical with insulin and could be separated from unreacted A and B chains in one step.

That the B chain of insulin cross reacts with anti-insulin antibodies, whereas the A chain does not[7], formed the basis for our new method of resynthesising insulin from the two chains. This method also involved the participation of antibodies (Fig. 1). During resynthesis of insulin from the isolated chains, a major product formed is a polymer consisting mainly of disulphide-linked B chain molecules[8]. Thus, active insulin can be obtained in good yield only if the polymerisation of the B chain is prevented. We assumed that S-sulphonate B chain, when bound to Sepharose-coupled anti-insulin antibodies, could no longer polymerise on reaction with reduced A chain if the distance between the B-chain molecules on the solid matrix was too large for inter-B chain disulphide bridges to form. Furthermore, antibody-bound S-sulphonate B chain was presumably fixed in a conformation identical or nearly identical to that of the B chain in the insulin molecule. This would to a great extent assist the 'parallel alignment' of reduced A chain and the closing of the right disulphide bonds to give active insulin.

Anti-insulin antibodies were prepared by injecting each of six guinea pigs with a suspension of 1.2 mg pig insulin in a mixture of 0.1 M Na_2HPO_4 (0.7 ml, *p*H 7.21) and Freund's complete adjuvant (0.3 ml). Sera were obtained by heart puncture 30 d after immunisation, and assayed using the immunodiffusion test[9] against pig insulin. The IgG fraction of strong sera was isolated using the procedure of Levy and Sober[10]. The concentration of purified antibodies was 6.4 mg ml^{-1}. To 22 ml of this solution 5 g freshly BrCN-activated Sepharose 4B was added, and the antibodies were coupled to the solid support by the method of Axen *et al.*[11]. After careful washing, an aliquot of the antibody–Sepharose gel was subjected to acid hydrolysis (6 N HCl, 105–110 °C, 24 h) followed by amino acid analysis. This showed that 0.054 µmol IgG was bound per g of Sepharose. Since there are two antigen-binding sites per antibody molecule the maximum capacity of the antibody–Sepharose for insulin or insulin B chain was 0.108 µmol g^{-1}.

S-sulphonate chains were prepared from natural insulin and separated on Dowex 50 as described previously[8]. B chain-bi-S-sulphonate ($B(S\text{–}SO_3^-)_2$; 7.65 mg; 2.125 µmol) was added to 5 g antibody–Sepharose in 0.01 M Tris-HCl, *p*H 8.3 (total volume 10 ml). The mixture was stirred for 3–4 h and then filtered. The gel containing 0.076 µmol antibody-bound B chain was washed thoroughly with the same buffer. From the combined filtrates, unbound $B(S\text{–}SO_3^-)_2$ was recovered. Tetrathiol A chain was prepared from $A(S\text{–}SO_3^-)_4$ by reduction with mercaptoethanol (100-fold molar excess per $S\text{–}SO_3^-$ group) in 5 M urea, *p*H 5. After 16 h a 15-fold amount of acetone containing 1.4% (v/v) 1 N HCl was added to precipitate the reduced A chain. The precipitate was centrifuged

Fig. 1 Combination of insulin chains on Sepharose-coupled anti-insulin antibodies. AIA, anti-insulin antibody; $A(SH)_4$, tetrathiol A chain; $(S\text{–}S)A(S\text{–}S)_2B$, combination product with one intrachain and two interchain disulphide bonds.



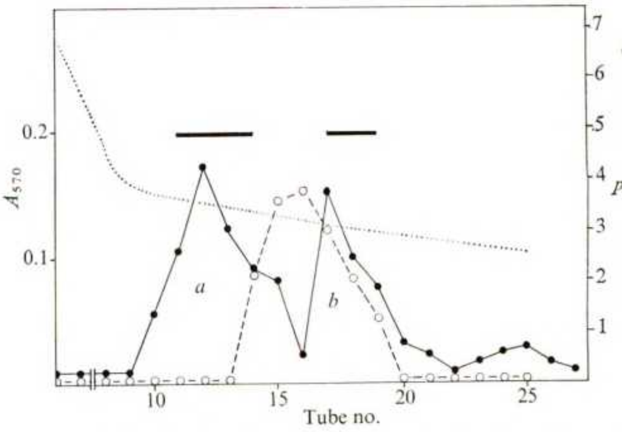


Fig. 2 Gradient elution of natural insulin (○) and recombination products (●) from anti-insulin antibody–Sepharose column (3.2 × 1.3 cm). Solvents used were 0.01 M Tris-HCl (*p*H 8.3, 40 ml) and 1 M acetic acid (*p*H 2.6, 40 ml)[2] (volume per tube approximately 1.5 ml). From each tube a 0.5-ml aliquot was removed for alkaline hydrolysis[13] followed by the ninhydrin reaction. Extinctions were read at 570 nm. By comparison with standard curves the protein content of tubes 11–14 (*a*, $B(S\text{–}SO_3^-)_2$) was found to be 0.159 mg or 44.2 nmol, that of tubes 17–19 (*b*, insulin) was 0.102 mg or 17.8 nmol. The total amount of B chain bound by the antibody–Sepharose column was 0.076 µmol compared with the maximum capacity of 0.540 µmol. The antibody–Sepharose column was used repeatedly. All elution patterns were identical to that shown above. In later runs $B(S\text{–}SO_3^-)_2$ and insulin could therefore be localised by measuring the *p*H value of each fraction of the eluate.

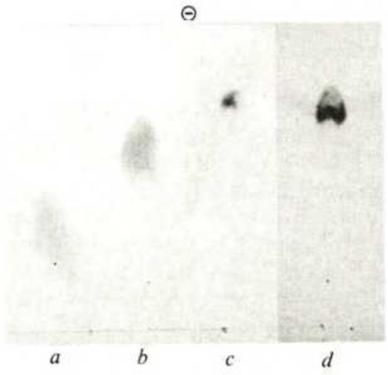

Fig. 3 Electrophoresis of recombination products and natural insulin on cellulose-coated thin-layer plates (20 × 20 cm) in 1.2 M formic acid and 2 M urea, *p*H 2.2, at 600 V for 50 min. The plates were sprayed with Pauly reagent. *a*, A chain-bi-disulphide; *b*, unreacted $B(S\text{–}SO_3^-)_2$; *c*, resynthesised insulin; *d*, natural insulin.

off and dried *in vacuo*. Its sulphydryl content, determined using the Ellman reagent[12], was found to vary between 3.6 and 3.8 mol per mol reduced A chain. Reduced A chain (4.06 mg, 1.735 μmol) was dissolved in 0.01 M Tris-HCl, *p*H 8.3, the solution added to the $B(S\text{–}SO_3^-)_2$– antibody–Sepharose complex (volume of recombination mixture 12–13 ml) and stirred gently. After approximately 20 h no more sulphydryl groups were detected. The gel was filtered and washed carefully. Electrophoresis (Fig. 3*a*) showed that the only product present in the filtrate was A chain which had not reacted with the antibody-bound B chain but had been oxidised to give the bidisulphide derivative.

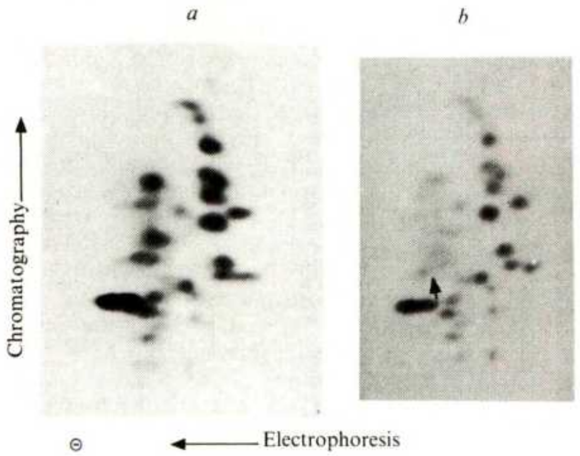

Fig. 4 Peptide maps of peptic digests of natural insulin (*a*, 0.12 mg) and recombined insulin (*b*, 0.03 mg)[14]. The digestion mixtures were applied on cellulose-coated thin-layer plates (20 × 20 cm) and were resolved by electrophoresis at 600 V for 75 min. in 12% acetic acid (v/v), adjusted to *p*H 1.9 with formic acid; and by thin-layer chromatography in 1-butanol–acetic acid–pyridine–water (30:6:20:24). The plates were sprayed with ninhydrin solution. The arrow in *b* marks the two weak spots that were not observed on the peptide map of pepsin-treated natural insulin.

The gel was then placed in a column (3.2 × 1.3 cm) and the products which were linked non-covalently to the antibody–Sepharose complex were eluted by a *p*H gradient (8.3–2.6), (Fig. 2). The first peak (absorption maximum at *p*H 3.6) contained unreacted $B(S\text{–}SO_3^-)_2$ as shown by amino acid analysis and electrophoresis (Fig. 3*b*). The absorption maximum of the second peak was at *p*H 3.15 and was close to that of amorphous natural insulin (Fig. 2). The material of peak *b* was desalted on Biogel P-2 in 0.05 M NH_4HCO_3 (yield, 0.018 μmol or 23.7% based on the amount of bound B chain) and then submitted to electrophoresis (Fig. 3*c*), peptic digestion followed by peptide mapping (Fig. 4), and amino acid analysis of an acid hydrolysate. Electrophoretic mobility (Fig. 3), peptide map (Fig. 4) and amino acid composition of product *c* agreed well with those of natural insulin.

Amino acid ratios were as follows (values reported for pig insulin[15] are in parentheses): Asp 2.7 (3); Thr 1.9 (2); Ser 3.2 (3); Glu 7.0 (7); Pro 1.0 (1); Gly 3.8 (4); Ala 2.8 (2); Cys 5.7 (6); Val 3.6 (4); Ile 1.6 (2); Leu 6.0 (6); Tyr 3.7 (4); Phe 3.0 (3); His 2.1 (2); Lys 1.0 (1); Arg 0.9 (1). In the fat cell assay[16,17] the product of peak *a* was inactive whereas the product of peak *b* (Fig. 2) had an insulin activity of 67%. The effective yield of authentic recombined material was thus 15.9% based on the amount of bound B chain.

Antigenic properties, electrophoretic mobility, and amino acid composition of recombination product and natural insulin were in good agreement. The peptide map of the recombined material showed two additional spots (Fig. 4*b*, arrow) but was otherwise indistinguishable from that of natural insulin, indicating that very few, if any, wrong disulphide bridges had formed during the coupling of A and B chains on the antibody–Sepharose matrix. The additional spots on the peptide map and the fact that the recombination product was not fully active may have been caused by the presence of a small amount of antibody eluted from the affinity column as insulin–antibody complex.

The chain combination method described here offers several advantages. Reconstituted insulin which was almost identical to natural insulin was obtained in one step without further purification. Unreacted A and B chains were isolated separately and could be easily reintroduced into the combination reaction. Finally, the antibody–Sepharose column could be used repeatedly. The possibility of using an anti-B chain-antibody–Sepharose matrix has not yet been studied.

Increase of glucagon receptors in hyperthyroidism

THYROID hormones influence the lipolytic response of rat adipocytes to adrenaline, glucagon, ACTH and TSH[1,2]. Krishna, Hynie and Brodie[3] provided evidence that hyperthyroidism is followed by an increase in the noradrenaline-sensitive adenylate cyclase without any change in phosphodiesterase activity. Subsequent investigations have shown that adenylate cyclase activity measured as fluoride stimulated activity is unchanged in hyperthyroidism[4] and confirmed that phosphodiesterase activity is normal[4,5]. Since the amount of hormone-sensitive lipase does not appear to be increased in hyperthyroidism[3] these studies indicate an action of thyroid hormones either on the hormone receptors for lipolytic hormones or on the transmission of the hormonal message from the receptors to adenylate cyclase. This prompted the present study in which we found that hyperthyroidism was associated with an increased binding of glucagon to fat cells as well as increased glucagon stimulated production of cyclic AMP and glycerol.

Male Wistar rats (120–175 g) were rendered hyperthyroid by daily subcutaneous injections of 20 μg triiodothyronine (T3) (Glaxo) for 8 d. Paired litter mates received in the same period injections of the vehicle for T3. Epididymal

Pure Che[illegible]stry Library

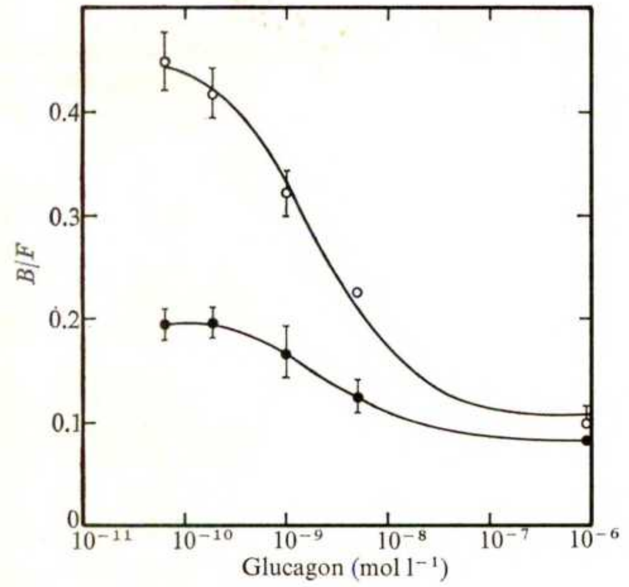

Fig. 1 Binding of glucagon to fat cells from a T3-treated (○) and a control (●) rat. Fat cells (10 µl ml^{-1}) were incubated at 37 °C in a Krebs–Ringer buffer with 25 mM HEPES (*p*H 7.4) and 1% of human serum albumin (Behringwerke) with ^{125}I-labelled glucagon or 0.18 nM ^{125}I-labelled glucagon plus unlabelled glucagon to give the indicated concentrations. After 30 min of incubation 6 aliquots of the cell suspension were transferred to microtubes containing approximately 100 µl of silicone oil and the cells were separated from the medium by centrifugation through the oil in a Beckman Model 152 Microfuge at 2,500*g* for 1 min. After cutting through the oil layer the cells and aliquots of the medium were counted for ^{125}I-activity. The ordinate is expressed as ^{125}I-activity per cells divided by ^{125}I-activity per l medium. Bars represent s.d., $n = 6$.

and perirenal fat pads were then removed and suspensions of isolated fat cells prepared[6].

Binding of glucagon to the isolated fat cells was measured at equilibrium by the displacement of ^{125}I-labelled glucagon (NOVO, Copenhagen, Denmark) by unlabelled glucagon. Cells were separated from medium by centrifugation through a silicone oil and counted for radioactivity in a gamma counter with a background of 3 c.p.m. and an efficiency of 35% (ref. 7). The number of glucagon receptors were calculated from a computerised fit of the experimental data[7], since the binding of glucagon to the receptor can be described as a reversible binding between the glucagon molecule and a single class of receptors[8].

Figure 1 shows binding curves for glucagon to fat cells from a hyperthyroid and a control rat. The binding of glucagon was measured in seven consecutive, paired experiments. The mean number of glucagon receptors on fat cells from control animals were 260±161 (s.d.) pmol per l cells, $1.8\times10^4 \pm 1.5\times10^4$ per cell and 1.6±1.1 per µm^2 cell surface; the corresponding values for fat cells from T3 treated rats were 658±331 pmol/l cells ($P<0.01$ by a paired two-tailed Student's *t* test), $2.8\times10^4 \pm 1.6\times10^4$ per cell ($P<0.05$) and 3.5±1.8 per µm^2 cell surface ($P<0.01$). Calculated as percentage of control values, the hyperthyroid fat cells possessed 227±101% (s.d.) glucagon receptors per l cells ($P<0.01$), 233±116% per cell ($P<0.05$) and 255±100% per µm^2 cell surface ($P<0.01$). Variations in cell size could not account for the differences between the two groups since mean cell diameter was virtually the same in some experiments. The dissociation constant (K_d) for the binding of glucagon was nearly identical for the two groups investigated (mean value 2.0 nM for controls and 2.2 nM for T3 treated). The degradation of glucagon measured as the ^{125}I-activity in a trichloroacetic acid supernatant was not changed by treatment with T3.

The glucagon stimulated production of cyclic AMP and glycerol was measured in order to study if the increased binding was reflected in the physiological response to the hormone. Figure 2 shows the correlation between the amount of glucagon receptor per l cells and the amount of cyclic AMP measured in the presence of 10^{-6} M glucagon. There is a highly significant correlation between these two parameters ($r=0.877$, $P<0.001$). Figure 3 shows the correlation between the amount of glucagon receptors and the production of glycerol in the presence of 10^{-6} M glucagon ($r=0.838$, $P<0.001$).

These results suggest that the increased glucagon stimulated production of cyclic AMP and glycerol in hyperthyroid fat cells is a consequence of an increased binding of hormone. The increased biological response to other lipolytic hormones might be explained by a similar increase in the number of receptors. To investigate whether T3 could also exert an effect on the binding of non-lipolytic hormones, we studied the specific binding of insulin, measured at a concentration of 0.7 nM insulin, in the same experiments where binding of glucagon was determined. The amount of specifically bound insulin was correlated to the amount of glucagon receptors ($r=0.816$, $P<0.001$). This increase in binding of insulin concomitant with the increase in glucagon receptors occurred without changes in the unspecifically bound insulin, and without changes in the K_d for insulin in three experiments where this was determined.

As intravenous injection of glucagon is followed by a supranormal rise in plasma cyclic AMP in patients with hyperthyroidism[9,10] and adrenaline causes supranormal urinary excretion of cyclic AMP in these patients[11], it seems reasonable to suppose that the observed effect is not confined to the glucagon and insulin receptors of fat cells from experimentally hyperthyroid rats.

Rosenqvist[12] demonstrated that the catecholamine receptors of fat cells from hypothyroid patients changes from

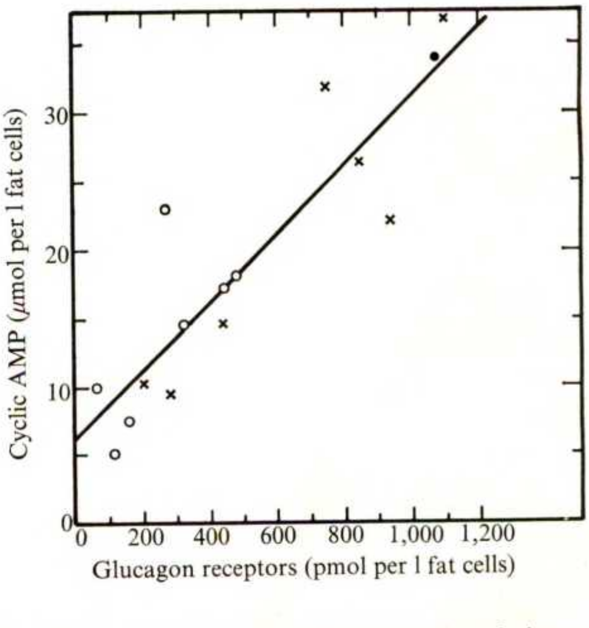

Fig. 2 Relationship between the calculated number of glucagon receptors and the glucagon stimulated cyclic AMP production. Fat cells from T3-treated (×) or control (○) rats were incubated at 37 °C in a Krebs–Ringer buffer with 25 mM of HEPES (*p*H 7.4), 1% human serum albumin, and 2.5 mM of theophylline in the presence of 10^{-6} M glucagon. After 330 s the incubation was stopped by addition of an equal volume of boiling EDTA (20 mM) and the mixture was boiled for another period of 330 s. Cyclic AMP was determined by a competitive protein binding assay[15]. The number of glucagon receptors was calculated from binding curves as shown in Fig. 1. The correlation coefficient between the two parameters is 0.877, $P<0.001$.

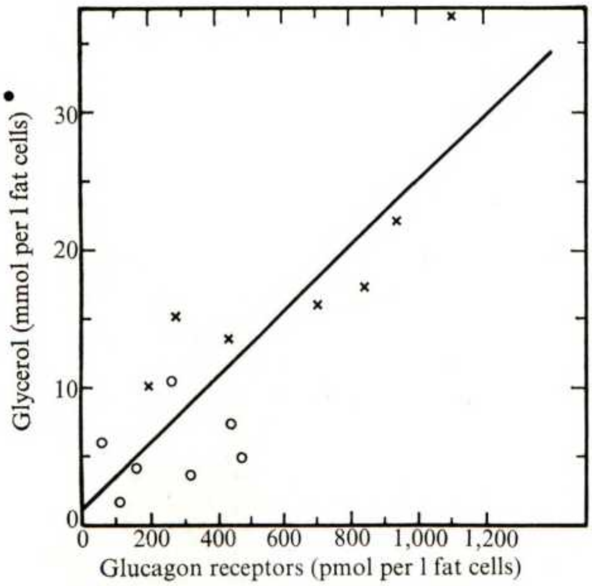

Fig. 3 Relationship between the calculated number of glucagon receptors and the glucagon stimulated production of glycerol. Fat cells from T3-treated (×) or control (○) rats were incubated for 60 min. at 37 °C in a Krebs–Ringer buffer containing 25 mM HEPES (*p*H 7.4), 2% of human serum albumin and 10^{-6} M glucagon. The incubation was stopped by addition of double volumes of 87 mM $ZnSO_4$ and 83 mM $Ba(OH)_2$. Glycerol was determined by a double enzymatic fluorometric assay[16]. The number of glucagon receptors was calculated from binding curves as shown in Fig. 1. The correlation coefficient between the two parameters is 0.838, $P < 0.001$.

predominantly β adrenergic to α adrenergic characteristics, and similar findings have been reported in the hearts of hypothyroid rats[13]. These results and the present study suggest that thyroid hormones are important regulators of the properties of hormone receptors located to the plasma membrane. Other examples of hormonal regulation of hormone receptors has been discussed by Tata[14].

This investigation was supported by a grant from the NOVO foundation.

Simultaneous detection of two cell populations by two-colour fluorescence and application to the recognition of B-cell determinants

CELL separation techniques, the possibility of recognising different markers by immunofluorescence and functional tests, have subdivided cells once thought to be a homogeneous group into different subclasses. This development has been most prominent for the so-called mononuclear cells. A difficulty inherent in the classification of such subclasses (of, for example, mononuclear cells) is that it is often almost impossible to determine precisely what percentage of the cells belongs to a certain subclass, and whether the sum of the subclasses is equal to, lower than or even higher than 100% of the total of the cells analysed. A typical recent example was the identification of the "null" or K cell[1,2]. Such analysis is greatly facilitated if we analyse a cell suspension stained with two or more different fluorescent dyes visible at the same time. This is feasible.

With the use of a monochromatic 50-W light source (HBO 50 W/a.c.) an LP455 and SP490 excitation filter combination, an FT510 dichroic mirror and LP520 barrier filter, the green fluorescence of isothiocyanate and the red fluorescence of rhodamine or ethidium bromide become visible simultaneously.

We have exploited these techniques to develop a rapid, simple and sensitive method of recognising polymorphism of B-cell determinants. Interest in these B-cell determinants (which are called Ia determinants in the mouse) is growing rapidly. They may be directly involved in T–B cell interaction in the immune response[3,4], code for disease predisposition[5] and the MLC-stimulating determinants[6] and determine allograft survival[7]. Most information on the genetics and possible biological importance of these B-cell determinants has been collected in the mouse[8], but information in man[6] and the rhesus monkey[9] is rapidly growing. Although B-cell determinants were identified virtually at the same time in the mouse and in man[10–13], the study of these antigens in man was hindered by the lack of sera and, especially, appropriate techniques to detect them. For routine work in man only peripheral blood lymphocytes can be used and here the proportion of B cells can be as low as 5–10%. Although the original enriching process by T-cell rosetting with SRBC and Ficoll–Isopaque gradient centrifugation[14] has been improved by the addition of papain or dextran (ref. 15 and W. Bodmer, personal communication), it remains (especially if the starting material contains a low percentage of B cells) a cumbersome, time-consuming and not fully predictable procedure. For this reason, a modifica-

Table 1 A comparison of the long B-cell complement-dependent cytotoxicity test[14] and the two-colour B-cell test

		Long B-cell cytotoxicity		
		Positive	Negative	Total
Two-colour B cell	Positive	58	10	68
	Negative	9	103	112
		67	113	180
			χ_1^2 (Yates) = 104.8 $P = < 0.000001$	

These data illustrate the excellent agreement between the two techniques and provide also information on the reproducibility of B-cell typing. The discrepancies were mainly caused by 2 of the 15 sera tested and were partly due to anti non-B cell cytotoxicity which cannot be recognised in the long B-cell complement-dependent cytotoxicity test.

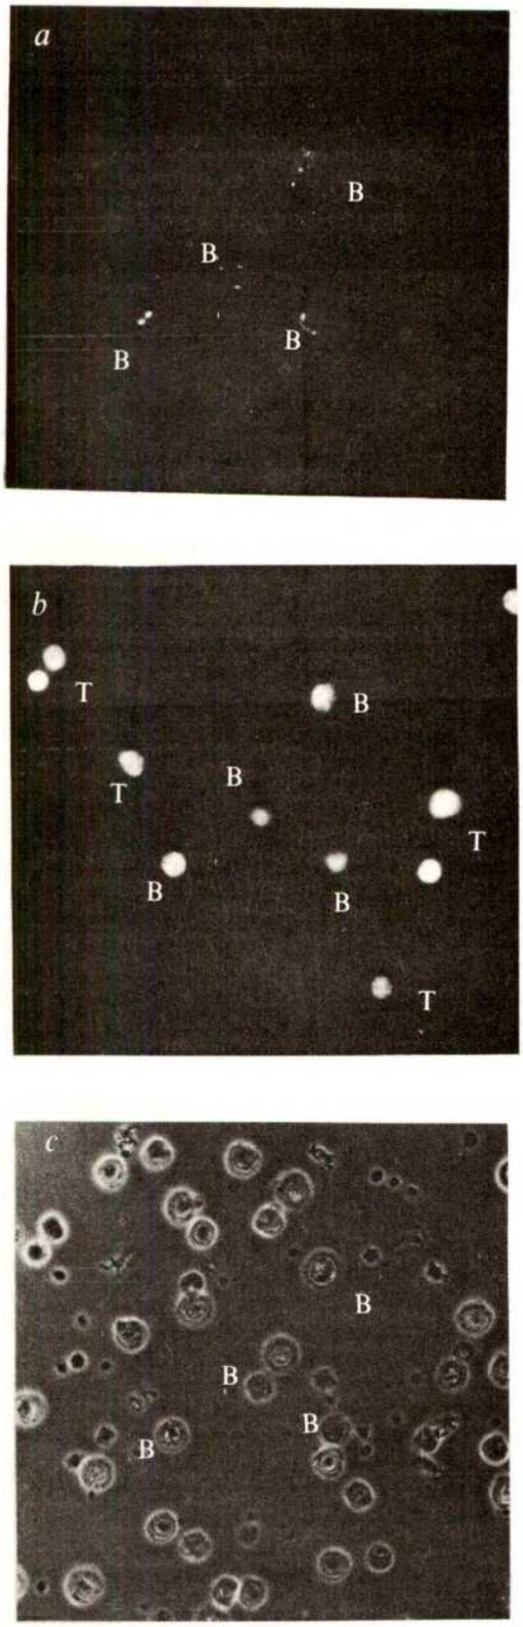

Fig. 1 Picture been taken of the green fluorescence of the immunoglobulins separately (*a*), from the red fluorescence of the nucleus (*b*). Note that also some non-B cells (presumably T cells) have been killed. The green and red fluorescence are depicted separately so that they can be seen in black and white only. When the test is read they are visible at the same time. *c*, The cells visible in phase contrast; many more cells were present than are visible in fluorescence.

tion lacking many of the drawbacks of the previously published method using two-colour fluorescence is described here.

In short, mononuclear cells were isolated from peripheral blood, the B cells were stained by fluorescein-conjugated anti-immunoglobulin and these so identified B cells (together with the unlabelled T and K cells) were incubated with anti-B-cell antibody and complement. Killed cells were stained by the addition of ethidium bromide. The exact procedure was as follows: 4 ml of heparinised blood was diluted twice in phosphate-buffered physiological saline (PBS) and 4 ml of this suspension was carefully layered on Böyum type Ficoll–Isopaque gradient[16]. The tubes were spun for 15 min at 1,000*g* and the mononuclear cells were collected from the interphase, washed 3 times in phosphate-buffered saline containing 1% bovin serum albumin (PBS–BSA 1%). Cells (4×10^6–6×10^6) suspended in 0.5 ml PBS+BSA 1% were incubated with 2 drops (0.05 ml) of goat anti-human immunoglobulin diluted 1 : 3 (Behringwerke AG, Marburg/Lahn, Germany) for 5 min at 37 °C. After three washings with PBS–BSA 1% the cells were adjusted to 8,000 mm^3. A sample (0.5 μl) of platelet-absorbed anti-B-cell serum was incubated in a Möller-Coates A/S tray (Moss, Norway) under paraffin oil with 0.5 μl of mononuclear cell suspension (4,000 cells) for 60 min at 20 °C. After that 2.5 μl fresh rabbit serum was added to provide an excess of complement factors and incubated for 2 h at room temperature. Finally, 0.5 μl of a 1 : 70 dilution of a stock solution (100 $\mu\text{g ml}^{-1}$) of ethidium bromide (Sigma) dissolved in EDTA 5% in saline was added. After putting a coverglass on the tray the reading was done on an inverted Leitz or Zeiss microscope with an epi-illuminator. Figure 1*a* shows a picture of the green fluorescence of the immunoglobulins, Fig. 1*b* the red fluorescence of the killed cells and Fig. 1*c* the corresponding phase-contrast picture. Note that also some non-B cells (presumably T cells) were killed.

The two-colour B-cell cytotoxicity technique was compared with the results obtained with the long B-cell cytotoxicity technique previously described. Excellent agreement was found between the two techniques (Table 1).

The red fluorescence of ethidium bromide can be strongly enhanced by switching the filterset in the two-wavelength vertical illuminator to green excitation (Table 2), which can be done with the new Leitz and Zeiss type of two-wavelength illuminators after Ploem quite easily[17]. It is thus possible to use about 4–8 times lower concentration of ethidium bromide than described above for blue excitation only. By using these lower ethidium bromide concentrations and the two-wavelength excitation method with subsequent excitation with blue followed by green light, it is also possible to make black and white micrographs for documentation. With green excitation of the same cell the red fluorescence of the (dead) nucleus is recorded. This two-wavelength procedure is also promising for future automation of this method since it provides sequential images which can be counted more easily.

As Fig. 1 shows, an advantage of the two-colour method is that it not only indicates whether a part of the mononuclear cells from peripheral blood is killed, but also whether there are B cells or also non-B cells killed. As a matter of fact, in our first trials with the new technique, two sera were identified which were thought to contain only anti-B-cell antibodies but could be shown to contain what looked like antibodies recognising a T-cell polymorphism as well. The method seems to be reliable and reproducible. Using the two-colour fluorescence method it was thus possible to facilitate greatly the recognition of the polymorphism of B-cell determinants. The advantage of this new method compared with the long B-cell complement-dependent lymphocyte toxicity technique is that it takes about 6 h (inclusive of reading) against 12 h for the

Table 2 Filter combinations for fluorescence microscopy of mononuclear cells stained with FITC conjugate and ethidium bromide

Combination	Excitation wavelength (nm)	Excitation filters	Barrier filter	Colour and strength of fluorescence	
1	Blue	$\text{LP}^{\times}455\text{–SP}^{+}490$	LP520	FITC green:	+++
				Ethidium bromide (higher concentration) red:	+++
2	Blue	LP455–SP490	LP520–SP560	FITC green:	+++
				Ethidium bromide (lower concentration) greenish:	±
3	Green	LP515–SP560	LP590	FITC:	±
				Ethidium bromide (lower concentration) red:	++++

$\text{LP}^{\times}$: long-wave pass filter; SP^{+}: short-wave pass interference filter (SP = German KP).

old method; and that one can be certain that if a fraction of the cells are killed, these cells are indeed B cells.

The point of more general importance is, however, that this approach makes possible the direct identification of two (or three) cell subclasses in one preparation. It is expected that this will improve the accuracy of the determination of the fraction of the different subclasses in cells only recently thought to be homogeneous.

This work was in part supported by the NIH, the Dutch Organization for Health Research (TNO), the Dutch Foundation for Medical Research (FUNGO) which is subsidised by the Dutch Organization for the Advancement of Pure Research (ZWO), and the J. A. Cohen Institute for Radiopathology and Radiation Protection (IRS).

Note added in proof: After completion of this letter it was pointed out to us that two-colour fluorescence has been described previously[18,19]. We compared our approach with that previously described and found that only our filter combination and protocol makes it possible to detect the B-cell antigens satisfactorily, because resolution was significantly better.

Helper T cells recognise antigen and macrophage surface components simultaneously

Although the T-cell antigen receptor has been shown to be as highly specific for antigen as the immunoglobulin receptor of B cells, considerable evidence suggests that genes other than those which code for immunoglobulins are involved in the recognition of antigen by T cells. Research in this area has centred on the role of gene products of the major histocompatibility complex (MHC), in particular of the I region of the H–2 complex of mice, in the antigen-specific receptor of T cells[1–3]. Other evidence has suggested that the specificity of T cells is determined by the simultaneous recognition of antigen and MHC cell-surface components. The best evidence for this comes from experiments with mice in which T-cell cytotoxic effectors specifically raised to the H–Y (ref. 4) or other minor histocompatibility antigens[5], viral antigens[6] or the hapten trinitrophenol (TNP)[7] were shown to recognise simultaneously both the antigen and the products of the *D* or *K* locus of H–2 expressed on the target cells. Investigations of the role of MHC gene products in the antigen-mediated interaction of T cells with B cells or macrophages (MΦ) can be interpreted similarly[1,8–15]. We present here evidence that in the mouse, helper T cells primed with the antigen, keyhole limpet haemocyanin (KLH), bound to the surface of MΦ, simultaneously recognise KLH and genetically controlled surface components of the MΦ. The rationale for our approch was as follows. In F_1 animals whose parents differ at loci controlling surface components (for example, H–2, Mls), if T cells could be primed with antigen bound to MΦ from one or the other parent, they should then cooperate preferentially with parental B cells and MΦ of the type used for priming.

To test these predictions we took advantage of the nonspecific association between protein antigens and the MΦ surface[12]. As described in the legend to Fig. 1, BDF$_1$ (C57B/6×DBA/2), C57BL/6, and DBA/2 mice were injected intraperitoneally with KLH. Peritoneal cells (PC), rich in MΦ were collected and used to prime three groups of BDF$_1$ mice. T cells isolated from these mice were tested for their ability to cooperate with BDF$_1$ or C57BL/6 B cells and MΦ in the response to TNP–KLH. All three groups of F_1 T cells were able to cooperate effectively with BDF$_1$ B-cells and MΦ (Fig. 1*a*). But as predicted, when tested with C57BL/6 cells and MΦ (Fig. 1*b*), F_1 T cells primed with KLH bound to C57BL/6 PC were the most efficient helpers, those primed with DBA/2 PC were the least effective and those with BDF$_1$ PC were intermediate.

Several control experiments have been carried out to eliminate alternative explanations for the results in Fig. 1. For example, it was possible that parental T cells contaminating the PC preparations were stimulated in the F_1 recipients and responsible for the subsequent properties of the primed helper cells. This

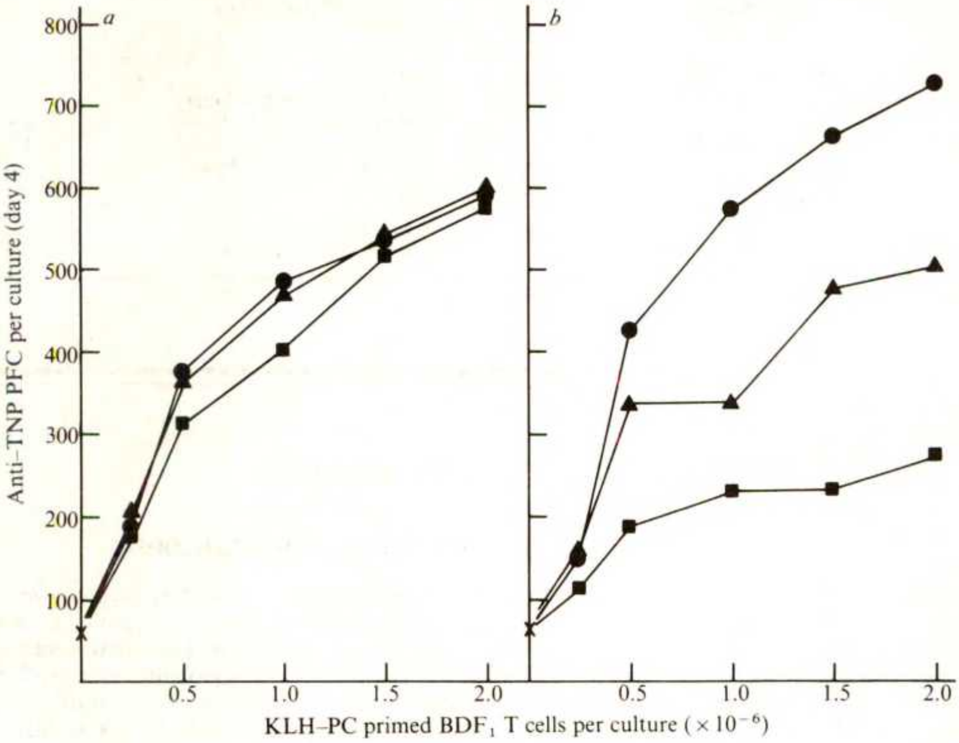

Fig. 1 Restriction of F$_1$ helper T cells in their ability to cooperate with parental B cells and MΦ. Groups of three BDF$_1$, C57BL/6 and DBA/2 mice (Jackson Laboratory) were injected intraperitoneally with 100 µg of KLH (Calbiochem) in 0.3 ml of balanced salt solution (BSS). After 4 h PC were collected by rinsing the peritoneal cavity with 4 ml of BSS containing 5% foetal bovine serum (FBS). The average yield was 3×10^6–4×10^6 PC per mouse. Pooled suspensions of each type of PC were washed twice with 5% FCS in BSS then resuspended to 5×10^6 cells per ml in BSS. Groups of three BDF$_1$ mice were injected with each type of PC (1.5×10^6 intraperitoneally and 1.5×10^6 intravenously). After 7 d a pooled spleen cell suspension was prepared from each group and depleted of B cells and MΦ on nylon wool columns[16]. The resulting T-cell preparations were titrated for KLH-specific helper activity as below. ▲, BDF$_1$, ●, C57BL/6 and ■, DBA/2 PC-primed BDF$_1$ T-cells. For B cells, BDF$_1$ and C57BL/6 mice were primed with 1.0 µg of TNP–LPS[17]. After 7 d spleen cell suspensions were prepared and treated with anti-T-cell serum and complement as described before[18] to deplete T cells but leave macrophages and hapten–primed B cells unaffected. Various combinations of the T-cell and B-cell preparations were tested in the the *in vitro* response to TNP–KLH. Cultures (0.5 ml) contained 4×10^6 B cells and macrophages, various numbers of BDF$_1$ T cells and TNP–KLH (0.05 µg ml^{-1}). After 4 d three identical cultures were pooled and assayed for anti-TNP plaque-forming cells (PFC). Both the culture methods and PFC assay have been described previously[18,19]. The responses (PFC per culture) are shown compared with the number of T cells added to the cultures. *a*, BDF$_1$ B cells and MΦ; *b*, C57BL/6 B cells andMΦ. For each titration the response of the B cells and MΦ cultured alone (×) is also shown. These figures represent the average responses obtained in six experiments with similar results.

possibility was eliminated by demonstrating that results identical to those in Fig. 1 were obtained even after pretreatment of the KLH–pulsed PC with anti-T-cell serum and complement before priming of F$_1$ animals (data not shown). In a second control experiment (Fig. 2) we tested whether, rather than a selective priming of helper T cells in the F$_1$, our results indicated a selective priming of specific suppressor cells. BDF$_1$ T cells which had been primed with KLH bound to either C57BL/6 or DBA/2 PC were prepared. The helper activities of these T cells and a 1:1 mixture of the two were assayed on C57BL/6 B cells and MΦ. As above, T cells primed with C57BL/6 PC were more efficient than those primed with DBA/2 PC. If the helpers primed with DBA/2 PC were ineffective because of the presence of suppressive activity specific for C57BL/6 cells, then the observed activity of the 1:1 mixture should be less than the calculated average of the responses obtained with the two helper preparations alone. In fact there was no difference between the calculated and observed responses, eliminating a role for a suppressive mechanism in this phenomenon.

We have begun experiments formally to identify the genes expressed in the parental cells that are responsible for imposing this restriction of F$_1$ helper T cells. For example, BDF$_1$ mice

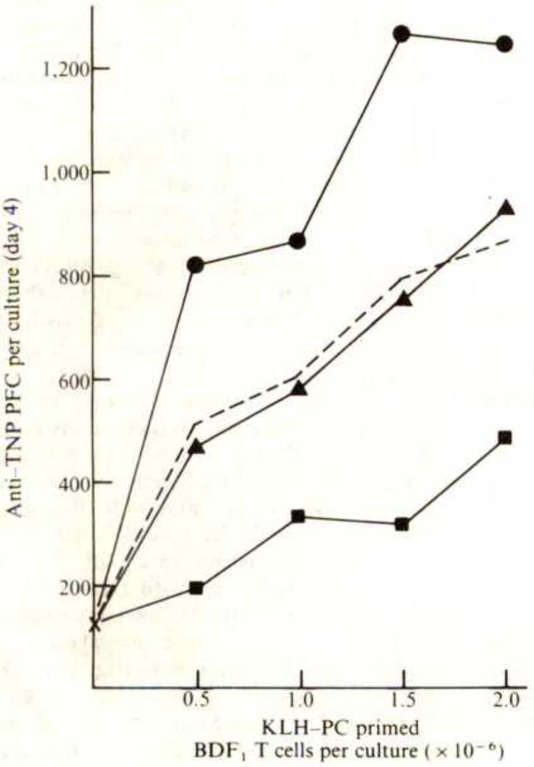

Fig. 2 Suppression is not the mechanism of restriction of F$_1$ T cells. BDF$_1$ T cells primed with KLH bound to either C57BL/6 (●) or DBA/2 (■) PC were prepared as in Fig. 1. Both T-cell preparations and a 1:1 mixture of the two (▲) were titrated on C57BL/6 B cells and MΦ. The calculated average of the responses seen with each T-cell preparation alone is also shown (- - - -). The response of B cells and MΦ cultured alone is shown (×).

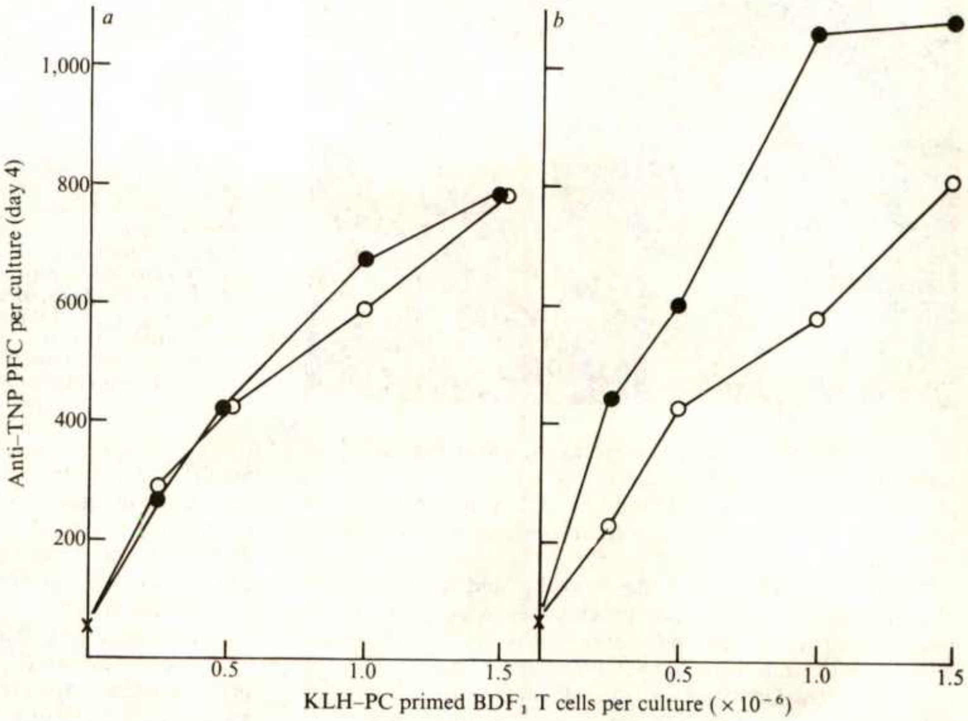

Fig. 3 Involvement of H–2-linked genes in restriction of F$_1$ T cells. BDF$_1$ T cells primed with KLH bound to either C57BL/10 (●) or B10.D2 (○) PC were prepared as in Fig. 1. These T cells were titrated on either BDF$_1$ (*a*) or C57BL/10 (*b*) B cells and MΦ as in Fig. 1. In each figure the response of B cells and MΦ cultured alone is shown (×). The figures represent the average responses seen in three similar experiments.

were primed with KLH bound to C57BL/10 (H–2^b) PC or to B10.D2 (H–2^d) PC. The resulting primed helper T cells were titrated for their ability to cooperate with either BDF$_1$ or C57BL/10 B cells and MΦ. The results (Fig. 3) indicate that although both F$_1$ T-cell preparations were equally effective when tested on BDF$_1$ B cells and MΦ, those primed with C57BL/10 PC were more effective with C57BL/10 B cells and MΦ than those primed with B10.D2 PC. Since these two strains are genetically identical except at the MHC, these results suggest a role for H–2-linked genes in the phenomenon. It is interesting that the differences in helper activity seen in Figs 1 and 2, where the priming PC differed at multiple genetic loci were greater than seen in Fig. 3 where the differences were confined to H–2-linked genes. These results may indicate that genes outside the MHC also contribute to the phenomenon.

Several previous studies of the role of histocompatibility gene products on antigen-mediated interactions between T cells and B cells or macrophages have suggested that such interactions require MHC identity between the cooperating cells[1,8,12]. Other studies[1,9–11,13,15] and the results presented here enable us to make an alternative interpretation of these findings. They suggest that T cells acquire the restricted ability to cooperate with B cells or macrophages of a particular MHC type, not as a result of some inherent genetic mechanism controlling interactions, but perhaps simply through the selection of relevant clones during the initial contact of T-cell precursors with an antigen in association with the surface components of the MΦ.

We thank Lee Harwell and George Berry for technical assistance. This work was supported by grants from the USPHS and the American Cancer Society.

Distribution of β_2 microglobulin and HLA in chorionic villi of human placentae

ANALOGIES are often made between transplantation and placental immunology. The role of histocompatibility antigens is of undisputed importance in transplantation immunology but it is not clear whether such antigens are important in pregnancy. Indeed, it is not known whether trophoblasts manifest histocompatibility antigens. If HLA antigens are relevant in pregnancy, it is of central importance to know if trophoblasts have these antigens. This is a difficult problem because human anti-HLA sera often contain other antibodies, and heterologous anti-HLA sera often lack precise HLA specificity[1]. But HLA has been shown to be invariably associated with β_2-microglobulin[2], and here we present data in support of the concept that human trophoblasts contain neither β_2 microglobulin nor

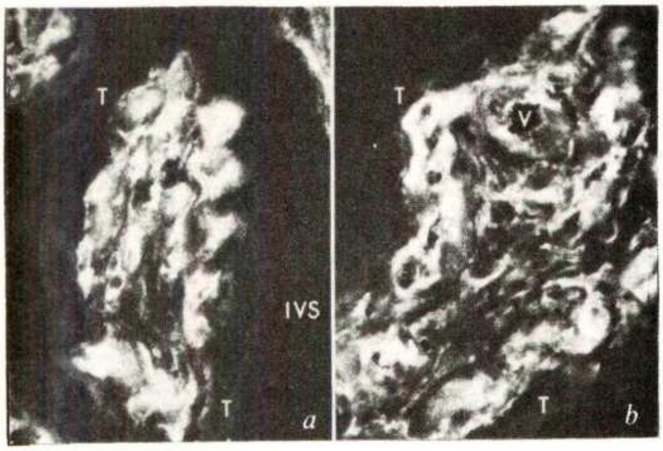

Fig. 1 Immunohistology of full term human placentae with antisera to: *a*, β_2 microglobulin, and *b*, HLA-2. Note negative trophoblasts (T) and positive staining of cells in mesenchymal stroma as well as vessel (V) endothelium. Thin (4-μm) sections were cut on a cryostat, air dried, and studied by indirect immunofluorescence[23] using an IgG fraction of rabbit antiserum to human β_2 microglobulin (Dakopatts A/S, Denmark) and rabbit anti-HLA sera from Dr A. Sanderson. Anti-HLA sera were prepared to HLA-1, HLA-2, HLA-7 and HLA-12 that were isolated by gel filtration, DEAE–cellulose chromatography and polyacrylamide gel electrophoresis. After absorption of these antisera with human erythrocytes, they were specific at low titre when tested for cytotoxicity with rabbit complement against human peripheral lymphocytes. Fluorescein isothiocyanate (FITC)-labelled sheep anti-rabbit Ig serum was obtained from Wellcome Reagents, Beckenham, Kent. Optimum dilutions of antisera (1:75) and conjugate (1:60) were determined by serial titrations[24] that gave minimum nonspecific staining and maximum specificity. Further details are given in the legend of Fig. 3. (Photographed at original magnification of ×400.)

HLA. Also, treatment with several enzymes has failed to reveal these antigens. In addition, we have not been able to identify either β_2 microglobulin or HLA on trophoblasts from 6-week or 13-week placentae or on placental tissues maintained *in vitro* for 5 d.

Thirty-two full term, one 6-week, and one 13-week placentae were studied. All pregnancies were normal and uncomplicated, all neonates were healthy, and all placentae were grossly and microscopically normal. Small pieces of tissue obtained from the central cotyledon within 15 min of delivery were either snap frozen or washed for 16 h at 4 °C with gentle rotation in minimum essential medium supplemented with glutamine, bicarbonate, 10% foetal calf serum (FCS) and antibiotics[3], and then snap frozen. *In vitro* cultures were prepared from tissues aseptically dissected from a 36-week placenta obtained by Caesarian section. Small pieces of tissue were placed on stainless steel grids supported in organ culture dishes (Bio-Cult Laboratories) containing 0.5 ml of medium RPMI supplemented with L-glutamine and 15% FCS (Bio-Cult) and incubated in 5% CO_2 in air. The medium was replaced daily, and the FCS concentration was reduced to 5% after the first day. Cultures were snap frozen after 1, 2 and 5 d in culture.

Tissues that were snap frozen either immediately or after washing overnight in growth medium consistently gave a characteristic pattern of staining for β_2 microglobulin by immunofluorescence. Trophoblasts and trophoblastic basement membranes (TBM) were unstained, and all other cells of the chorionic villus were positive (Fig. 1*a*). Using the antibody–peroxidase technique for light and

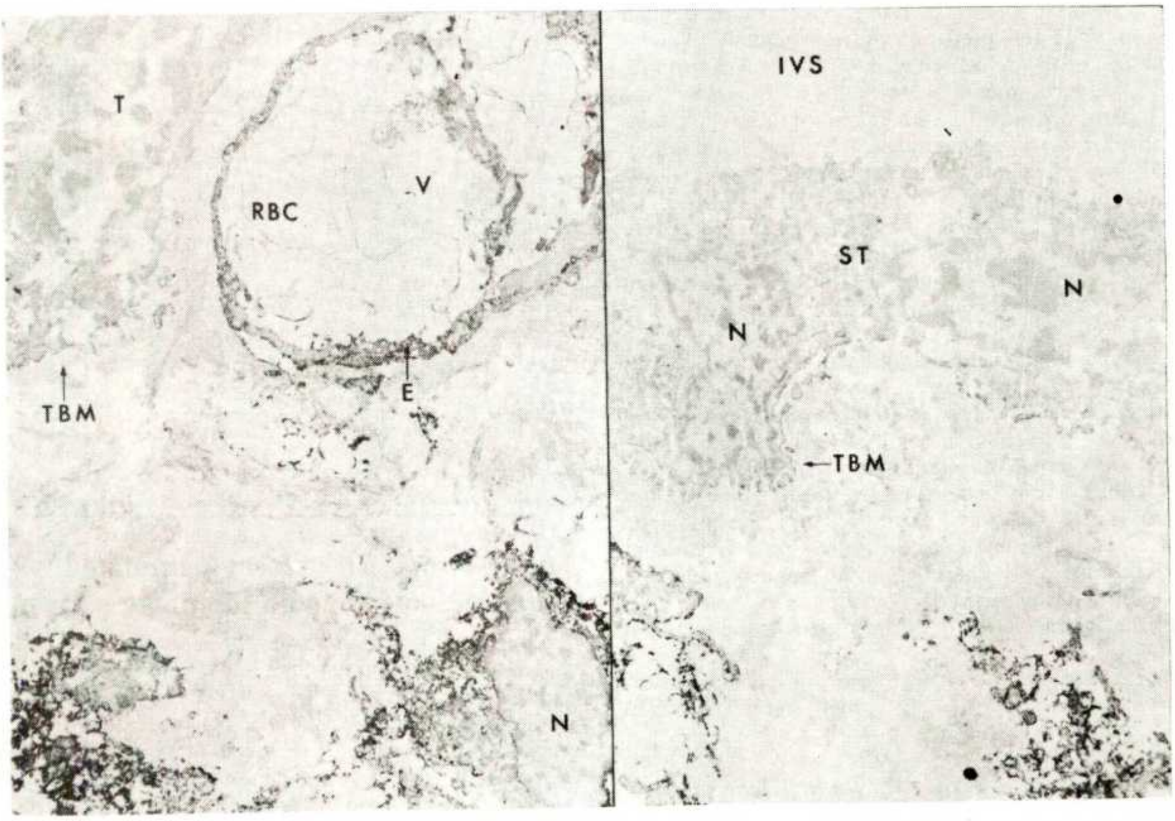

Fig. 2 Immunohistology of full term human placentae with antisera to β_2 microglobulin, achieved using the antibody–peroxidase technique by indirect staining for electron microscopy[4]. An AEI-EM-6B electron microscope was used. IVS, Intervillous space; RBC, red blood cell within vessel (V) in villous stroma; E, vascular endothelium; TBM, trophoblastic basement membrane; N, nuclei of trophoblasts; ST, syncitiotrophoblast. As it is not always possible accurately to differentiate between cytotrophoblasts and syncitiotrophoblasts by immunofluorescence, we restricted morphological definitions of trophoblasts to ultrastructural criteria[25]. Note negative trophoblasts and TBM, and positive cells and endothelium in villous stroma. Placentae were fixed for 30 min at 4 °C in 1% paraformaldehyde in 0.1 M PO_2, *p*H 7.4, containing 7.5% sucrose, and washed overnight in 13% sucrose and 0.1 M PO_4. (Original magnification ×3,000.)

Table 1 Effect of enzyme treatment on β_2-microglobulin staining

Treatment	Dose *	Time of incubation	Temp. (°C)		Immunofluorescence	
				Trophoblasts	Endothelium	Stroma cells
Neuraminidase (*Clostridium perfringens*)	3.6	1 h	20	−	++	++
	9.0	2 h	20	−	+	+
	9.0	3 h	20	−	+	+
Neuraminidase (*Vibrio cholerae*)	500	3 h	20	−	++	++
Collagenase (Sigma)	920	1 h	20	−	++	++
Hyaluronidase (Sigma)	920	1 h	20	−	++	++
	2,300	1 h	20	−	−	++
	4,600	1 h	37	−	−	−
Hyaluronidase (Fisons)	1,500	1 h	20	−	−	++
Trypsin (Sigma)	67	30 min	20	−	++	++
	67	1 h	20	−	+	+
PBS	—	2 h	20	−	+	+
	—	18 h	20	−	−	+

Collagenase was dissolved in 0.5 M Tris buffer, *p*H 7.5, containing 0.05 M Ca^{2+}, hyaluronidase in phosphate-buffered saline (PBS), *p*H 7.2 and trypsin in PBS, *p*H 7.4. Neuraminidase from *Cl. perfringens* was dissolved in PBS, and neuraminidase from *V. cholerae* (Koch-Light) was in 0.05 M acetate buffer, *p*H 5.5 containing 1% NaCl and 1% $CaCl_2$.

*Enzyme units ml^{-1}.

electron microscopy[4], it was possible positively to identify cells staining within villi, and confirm the absence of staining of trophoblasts, TBM and stromal connective tissues (Fig. 2). Tissues from 6-week and 13-week placentae as well as sections from a 36-week placenta that had been cultured *in vitro* for 5 d gave no trophoblast or TBM staining for β_2 microglobulin, but all cells on the foetal side of TBM in these tissues were positive (Fig. 3*a* and *c*). Treatment of cryostat sections of the above tissues with neuraminidase, hyaluronidase, collagenase or trypsin also failed to reveal β_2 microglobulin on trophoblasts or TBM by immunofluoroescence (Table 1), although exposure to large amounts of hyaluronidase and prolonged washing in phosphate-buffered saline diminished staining reactions of stromal and endothelial cells in some experiments (Table 1).

Several rabbit anti-HLA sera gave a pattern of staining by immunofluorescence identical to that obtained using anti-β_2-microglobulin serum. No positive staining of either trophoblasts or TBM was obtained with any of the anti-HLA sera, but cells in the villous stroma of all placentae being studied were stained with all these antisera (Figs 1*b* and 3*b*). The presence of HLA on endothelial cells of placental vessels is consistent with the report[5] of HLA on endothelial cells of the umbilical cord. Furthermore, our failure to identify HLA on trophoblasts is compatible with the observation[6] that human trophoblasts in cryostat sections do not bind concanavalin A. It is interesting that HLA is a glycoprotein that can be partially characterised by its ability to bind to concanavalin A-linked columns[7].

Whether or not trophoblasts manifest histocompatibility antigens is controversial. For example, Currie *et al.*[8] have shown that neuraminidase-treated A$_2$G ectoplacental cone cells injected into CBA mice cause the recipients subsequently to reject donor homografts in an accelerated fashion. Simmons *et al.*[9], however, using a similar experimental model were unable to confirm this, and our results also do not support the concept of masked histocompatibility antigens being present on human trophoblasts (Table 1). Loke *et al.*[10], using mixed cell agglutination reported that HLA antigens were present on trophoblasts, and Lawler *et al.*[11] favour an interpretation of HLA antigens on trophoblasts to explain their results of raised anti-HLA activity of paternal specificity in the sera of women with persistent trophoblastic disease after a first pregnancy with a hydatidiform mole. Perhaps mole tissues do contain HLA, but our experience with a large number of normal placentae suggests that HLA is absent from trophoblasts. The absence of HLA from trophoblasts is consistent with the results of Seigler and Metzgar[12] who used agglutination and antibody absorption techniques. Faulk *et al.*[13] have also reported that eluates prepared from exhaustively washed human placentae contain IgG that inhibits mixed leukocyte culture reactions without demonstrating HLA specificity, again suggesting an absence of HLA antigens from trophoblasts.

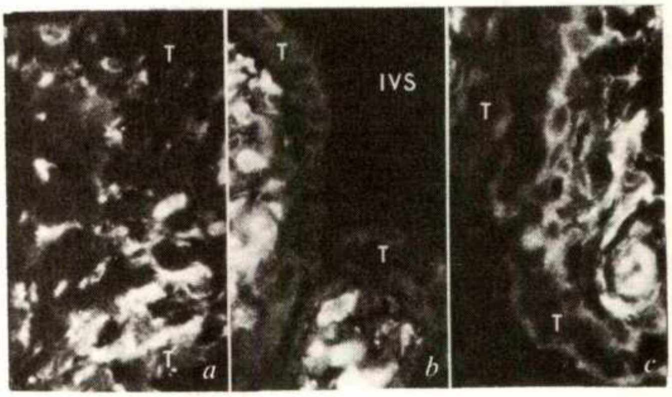

Fig. 3 Immunohistology of: *a*, 6-week placenta; *b*, 13-week placenta; *c*, 5-d culture of term placenta studied with antisera to: *a*, β_2 microglobulin; *b*, HLA-7; *c*, $\beta_2$microglobulin. Specificity and nonspecific-staining controls were done using immunoelectrophoresis, membrane immunofluorescence[3] with human leukocytes and red blood cells, and tissue immunofluorescence[23] using human spleen and rat kidney, liver, muscle and stomach as substrates. The anti-β_2-microglobulin serum gave one line in immunoelectrophoresis against concentrated urine from an oligouric patient with renal amyloid and was negative against five control urines of equivalent concentration. The anti-β_2 microglobulin and the anti-HLA sera gave bright membrane fluorescence at 1:30 dilution with human leukocytes but failed to stain human red cells. These antisera also stained leukocytes in human spleen but did not stain any of the rat tissues. Normal rabbit, sheep, and human sera were used as controls in all experiments. Sera were absorbed for 30 min at 18 °C before use by gentle rotation with an equal volume of washed, packed, sheep erythrocytes, and staining reactions were done according to standard methods[23,24]. Tissues prepared for immunofluorescence were examined by transmitted light using a Reichert Zetopan microscope fitted with a quartz–iodide light source, a Tiyoda wide-field dark-ground condenser incorporating a toric lens, and a FITC-3 Balzer interference primary filter and a Wratten 12 barrier filter. Photographs of transmitted fluorescence were made using Agfa-Gevaert CT18 (ASA 50) 35-mm film. Tissues were also examined by incident light using a Zeiss Photomicroscope 11 fitted with a Ploem epi-illuminator and an HBO 200 high-pressure mercury-vapour burner light source. Photographs of incident light were made using Gaf 500 (ASA 500) high speed 35-mm film. IVS signifies intervillous space, and correspondingly black areas on other photographs are also IVS. (Photographed at original magnification of ×400.)

Heyner[14], using direct immunofluorescence has reported H–2 antigens on cells of 6.5-d embryo cells but not on trophoblasts, and Searle *et al.*[15], using cytotoxicity reactions and a tailskin homograft model, found no evidence for histocompatibility antigens on trophoblasts, but did find H–2 antigens on cells of the embryonic sac. Billington[16] and Gardner *et al.*[17] have also questioned the presence of histocompatibility antigens on mouse trophoblasts, and Searle *et al.*[18], using the antibody–peroxidase technique for electron microscopy, have shown H–2 antigens on blastocysts which are lost from the trophectoderm at the time of implantation.

Experimental models that necessitate the physical separation of trophoblasts from other placental cells may contaminate trophoblast preparations with cells of the villous stroma that bear histocompatibility antigens. Similar technical considerations could account for the diversity of opinion regarding the presence of HLA or H–2 on trophoblasts. The geometrical relationship of trophoblasts to TBM and stroma is retained on cryostat sections studied by immunofluorescence, and using this approach we have been able to show a type of antigenic segregation in the distribution of β_2-microglobulin and HLA within chorionic villi. It is also important to know, however, whether or not histocompatibility antigens are present on the cell membranes of trophoblasts. This could technically be done by membrane fluorescence[3], using trophoblasts from *in vitro* cultures, but the possibility of contaminating trophoblast preparations with other villous cells still exists. What is needed is a membrane marker for human trophoblasts, and preliminary studies suggest that this might be transferrin[19].

These observations of the absence of histocompatibility antigens on trophoblasts suggest that analogies between transplantation and placental immunology are not entirely correct. There is no apparent mechanism to explain why trophoblasts lack β_2-microglobulin and HLA when these antigens are present on cells within mesenchymal stroma of the same organ. Genetic studies have shown, however, that the absence of β_2-microglobulin and HLA is not unique to trophoblasts. The B-cell-derived human Daudi lymphoblastoid line lacks both these proteins, but retains the capacity to express products of immune response-associated genes[20]. Goodfellow *et al.*[21] have shown that the gene responsible for β_2 microglobulin is not in the HLA region but is on chromosome 15, and Heyningen *et al.*[22] have reported that the genes responsible for mannose–phosphate isomerase and pyruvate kinase are also located on chromosome 15. We are studying the ability of human trophoblasts to manifest these enzymes. If the absence of β_2 microglobulin and HLA is associated with the specific capacity of human trophoblasts to avoid maternal recognition, then an understanding of the mechanism will perhaps be useful as an approach to biomedical and pharmacological studies of the more general problem of escape from immunological surveillance.

We thank Dr A. Sanderson for anti-HLA sera and information about their preparation and specificity; Dr Nancy Smith for 6-week and 13-week placentae; Drs Peter Johnson and Peter Page-Thomas for useful discussions; Mr Jack Dorling for assistance with antibody–peroxidase experiments; Mr Robin Faulk for technical assistance, and the WHO and the MRC for support.

Human milk samples from different ethnic groups contain RNase that inhibits, and plasma membrane that stimulates, reverse transcription

WE have compared human milk samples from American, Hindu and Parsi donors with a view to determining the relative amounts of reverse transcriptase inhibitors[1–5] present in them. Our intention was to find out whether samples from any specific ethnic group are advantageous for the study of type B virus-like particles in milk[2,6–8] and for purification of virus-associated enzymes. We also hoped that when sufficient data become available, such studies would be interesting from an epidemiological point of view, to test whether the inhibitors provide protection from mammary cancer. We have confirmed the presence of RNase in milk samples, and have observed variations in the level of RNase in samples from different ethnic groups. Careful examination has also revealed the presence of a protein factor, associated with plasma membranes in milk samples, that stimulates RNA-directed DNA synthesis (RDDS) *in vitro* in oncornaviruses.

To determine the effect of RNase-like inhibitors in different milk plasmas, each was examined for RNase content as judged by its ability to degrade ^{14}C-labelled yeast RNA (Table 1). The percentages shown against each group are averages of 15 independent experiments. Each sample tested for RNase activity was also tested for possible inhibitory activity in RDDS (see legend to Table 1). The mean values obtained are listed in Table 1 against the different ethnic groups. Although the mean values differ, the standard deviations are large and so it is difficult to place too much emphasis on the differences at this stage. With a view to minimising deviations arising from various factors involved in the enzyme assays, a more direct quantification was attempted.

Figure 1*a*, *b* and *c* shows the results on the basis of quantitative correlation for individual samples. In each graph all experimental points derive from a single set of experiments. The RNase-resistant counts for the individual samples are plotted on the abcissa, and the corresponding ^{3}H-TTP counts incorporated in the reverse transcriptase reaction using AMV pelleted through the milk samples are plotted directly on the ordinate. In a single set of experiments the same reaction mixture, with identical specific activity of ^{3}H-TTP, was used

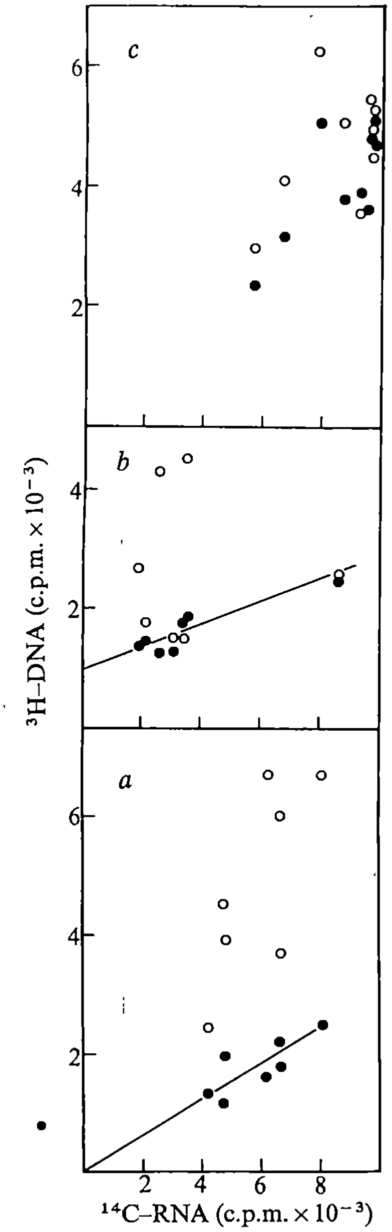

Fig. 1 Direct correlation of RNase content in milk samples and ^{3}H-TTP incorporation in reverse transcriptase reaction using AMV pelleted through the milk samples. Data from a single set of experiments from the different ethnic groups are presented. Milk plasma (2 ml) from each sample was halved. One half was used for incubation with ^{14}C-labelled yeast RNA, and the other for mixing with AMV (see legend to Table 1 and text). The AMV recovered after pelleting was halved, one half was used for primary reaction using endogenous template, and the other for the reaction with synthetic template. RNase-resistant counts are plotted on the abcissa and the ^{3}H-TTP incorporation in the parallel reverse transcriptase reactions plotted on the ordinate (see text). ●, Primary reactions; ○, reactions on synthetic template. *a*, American samples; *b*, Hindu samples; and *c*, Parsi samples. Specific activity of ^{3}H-TTP in primary reactions: 2,500 c.p.m. pmol^{-1}; 800 c.p.m. pmol^{-1} with synthetic template.

and the numbers obtained for ^{3}H-TTP incorporation were used directly to test possible correlation with the RNase-resistant counts. This provided a more direct comparison than plotting percentage RNase-resistance against percentage incorporation of label.

For samples from American and Hindu donors there was a direct correlation between RNase-resistant RNA counts in the milk plasma and DNA synthesis in primary reactions. This was not so for poly(dT) synthesis with poly(dT)·poly(rA) as template: which is understandable as the susceptibility to RNase of a single-stranded viral RNA template would be expected to be different from that of a synthetic hybrid template. Figure 1*c* shows that for the Parsi samples most points are grouped together towards the extreme right hand region of the curve. Very few points reach even towards the central region. Together with the data in Table 1 for the mean RNase level, these observations indicate a lower level of RNase in Parsi samples.

Although most milk samples contained inhibitors of reverse transcriptase, 40% of the Parsi samples did not inhibit RDDS. And in three out of 15 samples (Table 1) there was enhanced DNA synthesis compared with the control. Figure 2*a* shows the kinetics of an AMV reaction in which enhancement was observed. Samples belonging to this group have been tested repeatedly and the observation has been validated both for AMV and murine mammary tumour virus. Similar behaviour was observed for two of the 15 American samples, and later in several more Parsi samples (unpublished results). The stimulation observed in all these cases was RNase sensitive.

In a variation of this experiment the milk pellet prepared without AMV was taken up in 0.01 M Tris (*p*H 8.3), and then mixed with AMV instead of pelleting AMV through milk plasma. This had no effect on the observed results. If the milk pellets alone from these samples were tested for reverse transcriptase, there was no detectable reaction which could

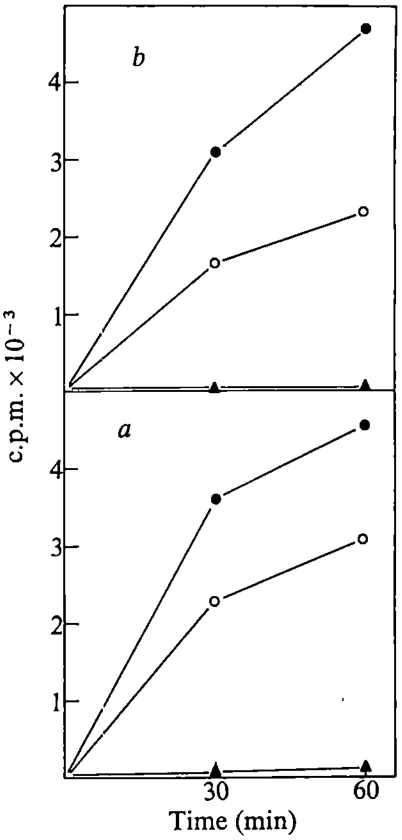

Fig. 2 Kinetics of stimulation of AMV primary reactions by plasma membrane factor from milk pellet (*a*, see text) and from milk fat suspension (*b*). ▲, Control reaction without AMV, but milk pellet alone (*a*) or fat suspension (*b*). ○, AMV primary reaction without any added milk component. ●, AMV primary reaction with milk pellet (*a*) corresponding to 60 μg of total protein, and with fat globule suspension (*b*) corresponding to 200 μg of fat with 10 μg of membrane-associated proteins as determined by Lowry method. In either case the milk factor was added to AMV before incubation with Nonidet P-40. The stock fat globule preparation was made by suspending freshly separated fat from milk plasma in 0.01 M Tris, *p*H 8.3, at 37 °C at a concentration of 20 mg ml^{-1}, and mixing thoroughly in a vortex mixer before pipetting out the required amount.

Table 1 Inhibition of RDDS by human milk plasma

Ethnic group	mg fat per ml	% RNase-resistant counts*	% DNA synthesis in AMV pelleted through milk plasma† Primary	Synthetic template
American	9.9±2.5	57.2±23.8	78.7±17.1	87.2±15.9
Hindu	17.7±7.8	62.1±14.3	63.3±18.5	76.1±14.3
Parsi	22.2±2.8	81.3±19.6	89.9±10.3	95.1±11.2

Hindu and Parsi milk samples were collected from maternity homes in Bombay and the samples were cooled immediately in ice, and later stored in liquid N_2. American samples were from the Michigan Cancer Foundation. The milk plasma was separated and the viral pellet prepared by the method of McCormick *et al.*[5]. The fat layer separated from a known amount of milk sample was extracted twice with a mixture of chloroform–methanol (2:1), the pooled extract was filtered and the fitrate was evaporated to dryness at 80 °C under a jet of dry nitrogen. The amount of dry residue left was determined by direct weighing and the content of fat in milk (mg ml^{-1}) was calculated. The relative amount of RNase in the samples was determined by incubating known amounts of ^{14}C-labelled yeast RNA (~8,000 c.p.m.) in 1 ml of the plasma for 30 min at 0 °C and determining the trichloroacetic acid (TCA)-precipitable counts after incubation. The percentage acid precipitable counts after incubation was determined for 15 samples each from the different ethnic groups and the mean values were calculated with standard deviations. Incubation of yeast RNA in control experiments at 0 or at 37 °C made no appreciable difference to the degradation of the RNA, and so we chose 0 °C as the temperature of incubation. Reverse transcriptase reactions were carried out as described before[8,14]. To determine the inhibition of AMV reaction by milk plasma, AMV (corresponding to 50 μg of viral protein) was mixed with 1 ml of milk plasma and kept at 0 °C for 30 min. This was layered over 4 ml of 20% glycerol in TNE (0.01 M Tris, *p*H 7.2, 0.1 M NaCl and 0.002 M EDTA) and the virus was pelleted by centrifugation at 234,000*g* for 30 min in a Beckman 50.1 rotor. The residue was taken up in 0.01 M Tris, *p*H 8.3, and used for reverse transcriptase reactions. ^{3}H-TTP incorporation from an equal amount of AMV (without milk plasma) pelleted through 20% glycerol was used to determine percentage DNA synthesis. The numbers reported are mean values from 15 determinations for each ethnic group. The specific activity of ^{3}H-TTP used was 2,500 c.p.m. p mol^{-1} for primary reactions, and 800 c.p.m. $pmol^{-1}$ for reactions with synthetic template.

* % Acid precipitable ^{14}C-RNA counts after incubation for 30 min at 0 °C.

† % ^{3}H-TTP incorporation in reverse transcriptase reactions using AMV pelleted through milk plasma compared with AMV pelleted through TNE.

account for the stimulation of AMV RDDS by an equivalent amount of pellet (Fig. 2*a*). Thus it is unlikely that the stimulation results from milk viral RNA-dependent DNA synthesis. We also examined the possibility that the enhanced synthesis was due to the protection of the AMV reverse transcriptase from proteolytic enzymes, as a consequence of the presence of additional proteins in the milk pellets. In control reactions in which an equivalent amount of either bovine serum albumin or casein was added in place of milk pellets there was no increase in the incorporation of ^{3}H-TTP.

In a separate experiment, a sample of milk pellet treated with Nonidet P-40, that stimulated AMV, was equilibrated with DEAE–cellulose for 30 min at 4 °C. The slurry was poured on to a column (0.7×3 cm), washed with buffer (0.01 M Tris' *p*H 8.3, 2 mM dithiothreitol (DTT) and 10% glycerol) containing 0.05 M NaCl, and eluted with the same buffer containing 0.4 M NaCl. RDDS stimulatory activity was present in the eluate. No activity remained either in the 0.05 M NaCl wash or in the loading solution draining out of the column after equilibration with DEAE–cellulose.

Table 2 Membrane marker enzymes in human milk samples

Marker enzyme	Specific activity of enzyme per mg protein Casein pellet	Ultracentrifuge pellet from milk plasma	Fat fraction
Alkaline phosphatase	0.326 μmol	0.283 μmol	0 107 μmol
Acid phosphatase	0.360 μmol	0.200 μmol	0.890 μmol
Xanthine oxidase	236 U	194 U	178 U

Membrane marker enzymes (selected from those listed in ref. 11) were assayed from different fractions of the milk samples. The casein pellet was obtained by centrifuging the milk sample at 5,000 r.p.m. in a Sorvall HB4 rotor for 20 min. The fat fraction is obtained by removing the top layer of fat, and the milk plasma pellet was obtained by layering the intermediate layer of milk plasma on 20% glycerol (see legend to Table 1) and isolating the pellet obtained by centrifugation at 234,000*g* for 30 min in a Beckman 50.1 rotor. To enrich the membranes, these fractions were suspended separately and uniformly in TM buffer (0.05 M Tris, *p*H 7.4, and 0 005 M $MgCl_2$) containing 20% sucrose. The fat suspension was treated differently. Skimmed fat (1 ml) was suspended in 5 ml of TM buffer and homogenised in a Potter–Elvehjem homogeniser (30 strokes). This was centrifuged at 10,000 r p.m. in an HB4 rotor for 10 min and the pellet was collected. The fat layer remaining at the top was collected, rehomogenised and pelleted in the same way twice more. The pellets were pooled and suspended in TM buffer containing 20% sucrose. The different suspensions in TM containing 20% sucrose were layered over a discontinuous sucrose gradient (TM) with 60% sucrose in the bottom overlain with 50, 40, 35 and 30% sucrose solutions. The samples were centrifuged at 1,380*g* in an HB4 rotor for 15 min. The band between 35 and 40% sucrose was collected. The membrane was isolated by repelleting after dilution with TM. This was dissolved in appropriate buffers for different enzyme assays. Alkaline phosphatase was assayed as described by Malamy and Horecker[15], acid phosphatase as described by Hollander[16] and xanthine oxidase by the method of Roussos[17]. Incubation was for 1 h at 37 °C.

We have made similar observations with the fat components. Reports have implicated lipid-associated inhibitor(s) present on milk particle isolates[1,4,9], but no systematic investigation of any such inhibitors has been reported. We observed variations in fat contents of milk samples from different ethnic groups (Table 1), and the freshly separated fat portions were tested for the presence of inhibitors. With samples for which the milk pellets showed strong inhibition of AMV reverse transcriptase, the addition of the corresponding fat suspension also showed inhibition. With samples that showed no inhibition, addition of the fat suspension had no inhibitory effect on ^{3}H-TTP incorporation in AMV reactions. There was, on the contrary, increased incorporation of ^{3}H-TTP in about 30% of such samples. This was clearly noticeable in the Parsi samples. Furthermore, samples showing enhanced DNA synthesis with milk pellets in AMV RDDS invariably stimulated the AMV reaction with the fat components as well (Fig. 2*b*).

We have observed stimulation of DNA synthesis[10] in the AMV reverse transcriptase reaction by plasma membrane preparations from chicken embryonic cells. To test the possibility that the stimulation in AMV reactions caused by milk plasma pellets, as well as fat globules, results from the presence of membranes in the preparations, these fractions were analysed carefully. Electron micrographs indicated the presence of small but definite amounts of membranes present in the plasma pellet preparations in the conditions[5-7] in which these pellets are made for detecting RDDS. In addition, both the pellets and fat fractions were layered on discontinuous sucrose gradients to enrich the membrane preparations which were assayed for marker enzymes (Table 2): the same preparations in turn stimulated AMV RDDS. Even when a milk pellet or fat fraction was not stimulatory at first, once the membranes were purified they were stimulatory There is evidence that the fat globules are covered by a double layer membrane which is very similar in composition to plasma membrane[11-13], suggesting that the stimulation from the milk pellet and from the fat component results from the same membrane-bound factor. This factor, like that isolated from chicken embryos[10], is not dialysable and yet is inactivated by heat. Experiments to enrich the stimulatory factor as well as to characterise the stimulated DNA product are in progress.

We thank Professor J. Beard for AMV.

Role of plasma membranes in stimulation of RNA-directed DNA synthesis

THERE has been considerable speculation about the small size of DNA transcripts (less than 10S) obtained by reverse transcription *in vitro* of 60–70S RNA from oncornaviruses[1–4]. On the basis of evidence suggesting that at least part of the virus-specific DNA synthesis could be taking place at the plasma membrane[5,6], we have examined the role of membrane-bound factors on RNA-directed DNA synthesis (RDDS). We report here the existence of a protein factor, associated with plasma membrane preparations from chick embryonic cells, that stimulates RDDS in avian myeloblastosis virus (AMV). The stimulated synthesis is sensitive to RNase, and the product DNA is 33–35S in alkaline sucrose gradients.

The effect of added plasma membrane on AMV incubated with Nonidet P-40 is shown in Table 1. The properties of the purified membrane preparations are shown in Table 2. There was a marked increase in ^{3}H-TTP incorporation in the primary reaction with AMV endogenous template. Similarly, there was increased incorporation of ^{3}H-dGTP when the synthetic template oligo(dG)·poly(rC) was used. In the absence of AMV there was no DNA synthesis with membrane preparation alone, or in conjunction with oligo(dG)·poly(rC). This rules out the possibility that any DNA-polymerising enzymes were present in the membrane and contributed to the increased synthesis.

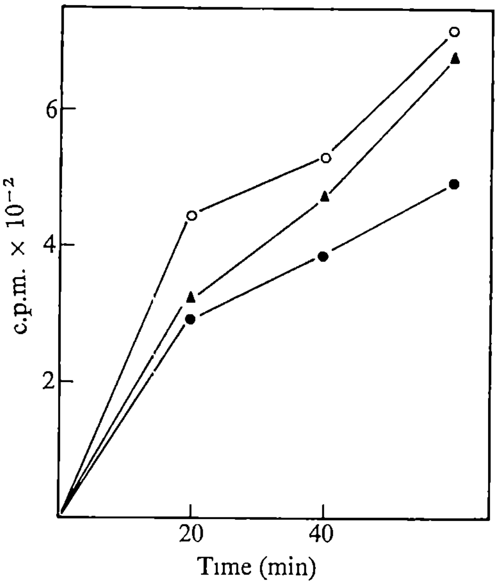

Fig. 2 Solubilisation of stimulation factor. Plasma membrane preparation containing 1 mg of proteins per ml was made 0.4% with respect to Nonidet P-40 and 0.1 M with respect to DTT. The mixture was incubated in ice for 30 min and was centrifuged in a Sorvall HB4 rotor at 7,500 r.p.m. for 10 min. The supernatant was removed and the pellet was resuspended in 0.01 M Tris, *p*H 8.3. After determining the protein concentrations in the supernatant and the pellet suspension, equivalent amounts of protein were added to AMV reverse transcriptase incubation mixtures (see legend to Table 1). From reaction mixtures containing 100 μg of membrane protein per ml, 30-μl samples were withdrawn at different times and the acid-precipitable radioactivity determined. ○, Supernatant; ▲, whole; ●, pellet.

Figure 1 shows the dependence of stimulation on the concentration of the membrane preparation in the reaction mixture. We found that in our experimental conditions the optimum concentration corresponded to 100 μg of membrane proteins per ml of reaction mixture. It was similar when a synthetic template was used. The reason for this is unknown. It is likely that there is a stimulatory activity and an inhibitory factor present in the unfractionated membrane proteins. Even after the stimulatory activity

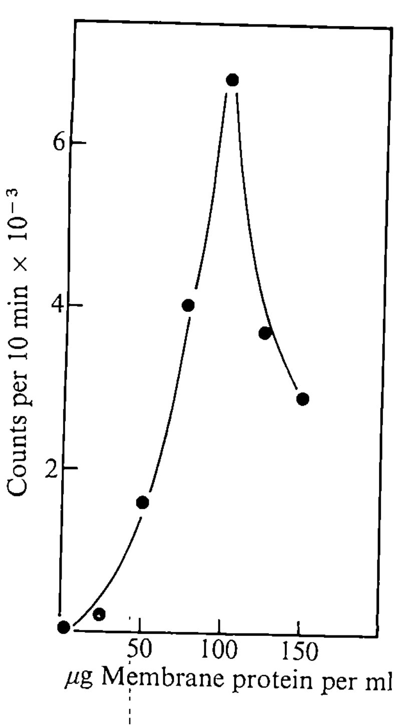

Fig. 1 Stimulation of RNA-directed DNA synthesis by AMV in presence of increasing amounts of plasma membrane. The results of primary reactions with endogenous RNA template are shown. Reactions were carried out in conditions described in the legend to Table 1. Incorporation of ^{3}H-TTP into TCA-precipitable radioactivity in 45-min reactions was determined, as were excess counts above control (reaction with no membrane protein present) and are plotted against different membrane concentrations.

Table 1 Stimulation of AMV reverse transcription by plasma membrane preparations

Reaction	c.p.m. of ^{3}H-TTP incorporated in 40 min
Primary reaction	
AMV control reaction	3,200
AMV+plasma membrane (120 µg protein per ml)	6,024
Membrane without AMV (120 µg protein per ml)	36
Reaction using oligo(dG)·poly(rC)	
AMV control reaction	6,172
AMV+plasma membrane (120 µg protein per ml)	21,399
Membrane without AMV (120 µg protein per ml)	81

Plasma membrane was prepared from 7–9-d-old chicken embryos as described in the legend to Table 2. The amount of total protein present in each preparation was determined by the Lowry procedure and purity was checked by marker enzymes (Table 2). The standard reverse transcriptase assay mixture contained, 5×10^{-2} M Tris, pH 8.3, 4×10^{-2} M NaCl, 8×10^{-3} M $MgCl_2$, 2×10^{-3} M dATP, dCTP and dGTP, and ^{3}H-TTP at 1,500 c.p.m. pmol^{-1} for the primary reactions. The mixture for the synthetic template reactions contained oligo(dG)$_{12-18}$·poly(rC) at a concentration of 10^3 µg ml^{-1}. Of the triphosphates these mixtures contained only cold dCTP (2×10^{-3} M) and ^{3}H-dGTP (500 c.p.m. pmol^{-1}). The membrane preparations (1 mg ml^{-1}) were made 0.4% with respect to Nonidet P-40 and 0.1 M with respect to dithiothreitol (DTT) and incubated separately at 0 °C for 30 min. Required amounts of this preparation were added to the standard reverse transcriptase assay mixtures before incubation at 37 °C. The primary reactions were in the presence of actinomycin D (50 µg ml^{-1}). The reactions described above were done using 50 µg of AMV preincubated for 10 min at 0 °C with 0.4% Nonidet P-40 and 0.1 M DTT. The total reaction volume was 100 µl. Samples of 30 µl were withdrawn after 0 min, 20 min and 40 min of incubation and the trichloroacetic acid (TCA) preciptable radioactivity present in the different samples was determined.

reaches saturation, the inhibitory activity may be increasing as membrane concentration increases.

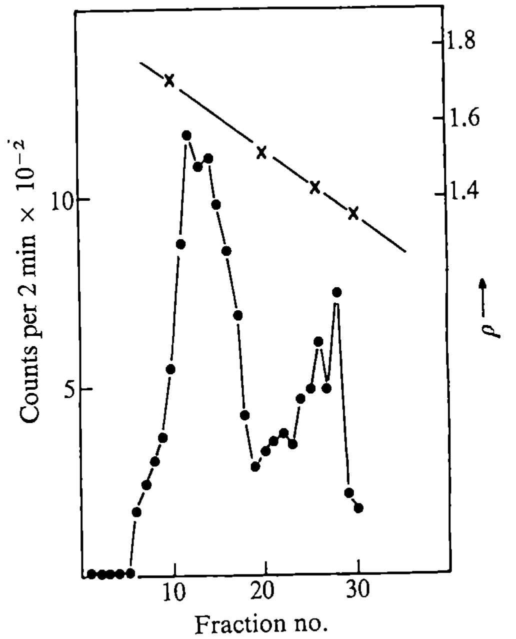

Fig. 4 Hybridisation of DNA product from a plasma membrane stimulated AMV primary reaction with high molecular weight AMV RNA. Purification of single-stranded DNA product and preparation of AMV high molecular weight RNA have been described before[16]. The incubation mixture for hybridisation contained, 50 µg of AMV RNA; 10,000 c.p.m. of purified ^{3}H-DNA; 0.45 M NaCl, and 0.002 M EDTA, pH 7.2 and 75 µl formamide in 150 µl. After incubation at 37 °C for 24 h, the solution was diluted with 2.35 ml of 5×10^{-2} M EDTA and 2.56 ml of saturated Cs_2SO_4. This solution had a refractive index of 1.375. It was centrifuged for 60 h at 20 °C using a Spinco SW50.1 rotor at 40,000 r.p.m. After centrifugation the contents were fractionated by bottom puncture of the Polyallomer centrifuge tube and the TCA-precipitable radioactivity in the fractions determined.

The stimulatory activity associated with the membrane preparations can be solubilised. When a preparation was centrifuged after incubation with Nonidet P-40 the activity was present in the supernatant. But, not all the activity was recovered (Fig. 2), some remained in the pellet fraction, although at a reduced level. In a different experiment, the membrane preparation from chick embryo cells, after treatment with Nonidet P-40, was centrifuged in a Sorvall HB 4 rotor at 7,500 r.p.m. for 10 min, and the supernatant was equilibrated with DEAE-cellulose for 30 min at 4 °C. The thick slurry was poured on to a column (0.7×2 cm), washed with buffer (0.01 M Tris, pH 8.3, 2 mM DTT, 10% glycerol) containing 0.05 M NaCl, and eluted with the same buffer containing 0.4 M NaCl. RDDS stimulatory activity was present in the eluate, and none remained in either the 0.05 M NaCl wash or the loading solution draining out of the column. The activity was destroyed by heating for 10 min at 100 °C and it was non-dialysable. These observations, together with the fact that stimulation was observed when a synthetic template was used with only two deoxynucleoside triphosphates in the reaction mixture, eliminate

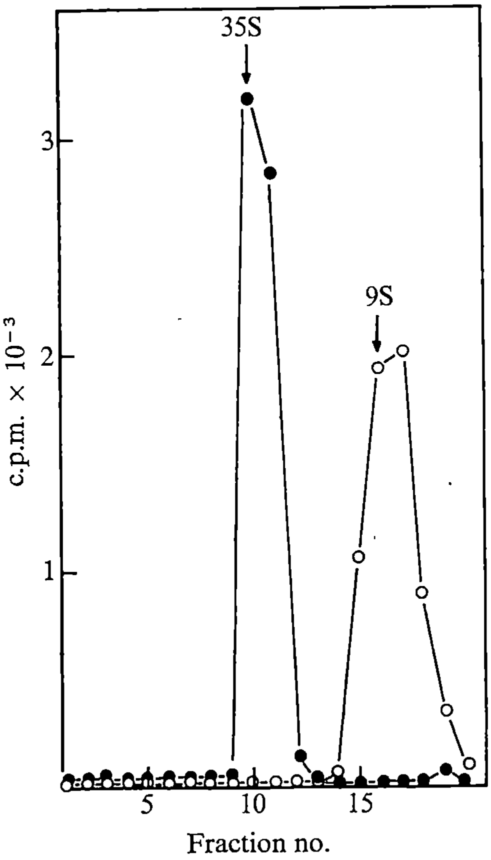

Fig. 3 Comparison of the size of DNA product of AMV reverse transcription in the presence and absence of plasma membrane preparations. The DNA products were made using reaction conditions described in the legend to Table 1. For size determination we have used reaction mixtures containing ^{3}H-TTP at 2,500 c.p.m. pmol^{-1}. After incubation for 60 min the reactions were stopped by the addition of sodium dodecyl sulphate to 1% and NaCl solution to 0.4%. The nucleic acid products were isolated by phenol extraction as described before[16]. The isolate was incubated with 0.3 M NaOH for 18 min at 37 °C and after cooling was layered on a 5–20% linear sucrose gradient (10^{-2} M Tris; 10^{-2} M EDTA; 0.7 M NaCl, and 0.3 M NaOH). Centrifugation was done in a Spinco SW50.1 rotor at 48,000 r.p.m. for 120 min. The gradients were fractionated and the TCA-precipitable radioactivity was determined. Purified DNA from phage PlKC, and *Haemophilus influenzae* phage (HPlC$_1$) were used as external markers in separate tubes, ●, DNA synthesised in the presence of plasma membrane (110 µg proteins per ml); ○, DNA synthesised in control reactions without added membrane proteins.

Table 2 Marker enzymes present in plasma membranes isolated from chick embryos

Enzyme	Specific activity per mg per h Homogenate*	Purified preparation	Enrichment factor
ADPase	1.02 μmol	2.31 μmol	2.3
5′-Nucleotidase	0.49 μmol	2.00 μmol	4.1
Na^+, K^+-ATPase	0.75 μmol	2.00 μmol	2.7
Alkaline phosphatase	0.16 μmol	1.40 μmol	8.8
CTPase	0.82 μmol	4.04 μmol	4.9
Succinate dehydrogenase	8.7 U†	2.1 U†	0.24

*Homogenate after filtration through cheesecloth (see below)

†Increase in A_{490} units; see ref. 15.

The membranes were made from 7–9-d-old chick embryos[8,9], which were dissected to remove internal organs, head and limbs. The tissue was minced, washed thoroughly with TM buffer (5×10^{-2} M Tris, *p*H 7.4 and 5×10^{-3} M $MgCl_2$) and homogenised by 30 gentle strokes in a Potter–Elvehjem homogeniser It was filtered through two layers of cheesecloth. It was centrifuged at 2,500 r.p.m. in a GSA rotor for 15 min and the pellet was resuspended in TM and placed on top of a discontinuous sucrose gradient in TM consisting of 60% sucrose in the bottom (4 ml) overlain with solutions containing 50% (4 ml), 40% (4 ml), 35% (10 ml), 30% (5 ml) and 20% (5 ml) of sucrose. The gradient was made in a cellulose nitrate tube for the Beckman SW27 rotor, but spun in an HB4 rotor at 1,380*g* for 15 min. The fraction that collected between 35% and 40% sucrose was withdrawn with a syringe and pelleted by centrifugation at 6,000*g* for 15 min after adjusting the sucrose concentration to 5%. This pellet was resuspended in TM and purified twice more by passage through the discontinuous gradient and isolation between 35% and 40% sucrose. The pellet obtained after the third discontinuous gradient was taken up in 30% sucrose in TM and placed over a different discontinuous gradient with 60% sucrose at the bottom (3 ml) overlain with solutions having 55% (3 ml), 50% (3 ml), 48% (6 ml), 45% (6 ml) 43% (4 ml), and 40% (4 ml) of sucrose and centrifuged at 90,000*g* for 90 min in an SW27 rotor. The membrane formed a band between 43% and 40% sucrose. This fraction was separated and the membrane pelleted by centrifugation at 6,000*g* for 15 min after adjusting the sucrose concentration to 5%. This was resuspended in the required buffers for the assay of marker enzymes. The amount of total proteins present in each preparation was determined by the Lowry procedure. ADPase and CTPase were assayed as described by Perdue and Sneider[10], Na^+, K^+-ATPase by the method of Post and Sen[11], 5′-Nucleotidase by the method of Morre[12], alkaline phosphate by the method of Malamy and Horecker[13], and succinate dehydrogenase by methods described by King[14] and Pennington[15].

the possibility that stimulation was due to a DNA or RNA contaminant in the membrane preparation.

The DNA product of the stimulated primary reactions was larger (33–35S in alkaline sucrose gradients (Fig. 3)). than the product synthesised in the absence of plasma membrane preparation. The distribution of size varied slightly from experiment to experiment· this could have resulted from variations in length of viral RNA template.

The hybridisability of the product was also examined. The results of hybridisation with 70S RNA from AMV are shown in Fig. 4. Most of the counts were present in the RNA and RNA–DNA hybrid density region The spilling over of the counts to the hybrid region when hybridisation was done with an excess of AMV RNA probably indicates the presence of full length DNA transcripts. Unlike small pieces of DNA hybridising to large RNA molecules, resulting in RNA–DNA hybrids with densities close to that of RNA, full length DNA or nearly full length DNA can form 1 : 1 RNA–DNA hybrids. This type of hybrid would band at a region with the mean density of DNA and RNA.

Based on these observations, we suggest that the stimulation of DNA synthesis is caused by a thermosensitive and non-dialysable factor associated with the membrane. But the method used to purify the membrane may also have purified some of the membraneous organelles of the cell, such as endoplasmic reticulum, for their density is very close to that of the outer plasma membrane. At present the mechanism of stimulation and chain elongation is not clearly understood. Experiments are in progress to determine whether the stimulation of the reaction is due to interaction of the factor with the template or reverse transcriptase. In this respect, the factor can be compared with the DNA binding proteins reported by Hung and Lee[7]. Rigorous characterisation (such as genomic complexity) of the longer DNA molecules synthesised in the presence of the membrane preparation is in progress. If the longer DNA molecule contains the same information as the viral RNA faithfully represented in the same proportion, such radioactive molecules will provide 'superior probes' in studies of viral gene expression in infected cells.

Ion effects on macromolecules in aqueous solution

APART from their nonspecific electrostatic interactions, ions can produce specific effects on the conformation and solubility of macromolecules in aqueous solution[1]. The relative effectiveness of anions and cations in altering macromolecular configurations is remarkably independent of the nature of the macromolecule and is generally referred to as the lyotropic or Hofmeister series. To explain the generality of the effects, the influence of the ions on the structure of the solvent has often been invoked, but as yet no theory has been able to link satisfactorily ion–water interactions with the effects of ions on macromolecules. We argue here that it is the effect of the ions on the empty volume of the solvent which underlies the Hofmeister series and we derive a simple thermodynamic equation which accounts for the effect of a salt on the transition temperature for a polymer chain aggregation process. To test the equation we have taken data from the literature relating to the cloud point of polyvinylmethylether (PVME; intermolecular aggregation); and to the thermal transition temperature of ribonuclease (intramolecular aggregation).

Aqueous solutions of PVME have a lower critical solution temperature or cloud point (T_c) at 34 °C—that is, above this temperature two immiscible phases are formed, one of which contains almost all the polymer in an aggregated form. On cooling the change is reversed but redissolution of the polymer is slow. Horne *et al.*[2] studied the effect of a number of salts on T_c and found that it could be either raised or lowered according

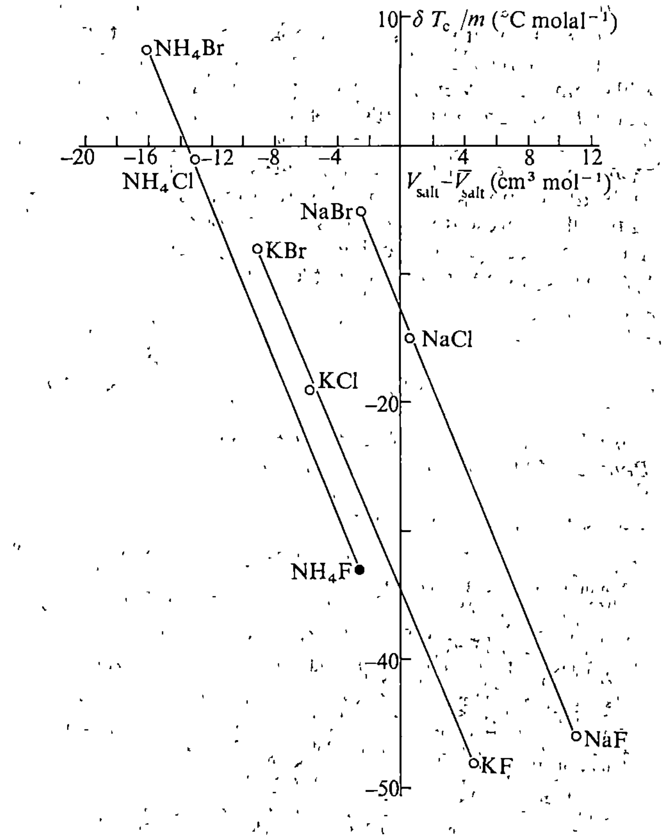

Fig. 1 Salt effects on T_c of a 2.5 weight % aqueous solution of PVME. ○, Ref. 2; ●, present work.

to the particular salt added and that often the change was approximately linear with salt concentration. Similarly, it has been shown that the temperature (T_m) of the midpoint of a cooperative transition involving the unfolding of the native ribonuclease molecule can be shifted up or down, often approximately linearly by increasing concentrations of neutral salts[3,4]. In both cases the rank order of molar effectiveness follows the Hofmeister series.

At either T_c or T_m we can write an equilibrium: dissolved polymer segments ⇆ aggregated polymer segments. The transfer from the dissolved to the aggregated state in water at a pressure P will involve changes in the partial molal internal energy ($\bar{U}$), volume ($\bar{V}$) and entropy ($\bar{S}$) of the polymer segments, which will be related to the transition temperatures by

$$T_{c,m} = (\Delta\bar{U} + P\Delta\bar{V})/\Delta\bar{S} \qquad (1)$$

For a salt solution in which $\Delta\bar{S}$ remains unaffected, the change in the transition temperature will be given by

$$\delta T_{c,m} = (\delta\Delta\bar{U} + P\delta\Delta\bar{V})/\Delta\bar{S} \qquad (2)$$

We shall neglect the temperature dependence of the partial molal quantities over the range $T_{c,m}$ to $T_{c,m}+\delta T_{c,m}$ and assume that $\delta T_{c,m}$ is solely determined by the salt effect. To calculate $\delta\Delta\bar{V}$ we consider the empty volume which exists in the solvent and which is defined by: observed volume − van der Waals' volume of the molecules[5]. Because of its hydrogen-bonded structure, water is exceptional in having a very large empty volume (about 46%), and Bernal and Fowler[6] pointed out that the main contribution to the volume change associated with the solution of ions arises from the collapse of this structure. If the polymer can utilise the voids in the solvent, we can write

$$-\delta\Delta\bar{V} = V_e(\text{water}) - V_e(\text{soln}) \qquad (3)$$

where V_e(water) is the empty volume existing in the volume of water containing 1 mole of transferring segments and V_e(soln) is the corresponding volume in the salt solution. By considering the transfer of a mole of segments from 1 kg water to 1 kg water + m moles of salt at a given temperature an expression for $\delta\Delta\bar{V}$ in terms of salt concentration can easily be obtained since

$$V = V_e(\text{water}) + 55.5\, V_{H_2O} \qquad (4)$$

$$m\bar{V}_{salt} + 55.5\,\bar{V}_{water} = m\,V_{salt} + V_e(\text{soln}) + 55.5\,V_{H_2O} \qquad (5)$$

where V is the observed volume of water, V_{H_2O} and V_{salt} are molar van der Waals' volumes, and $\bar{V}_{salt}$ and $\bar{V}_{water}$ are partial molal volumes. Subtracting (5) from (4) gives

$$V_e(\text{water}) - V_e(\text{soln}) = m(V_{salt} - \bar{V}_{salt}) + (V - 55.5\,\bar{V}_{water}) \qquad (6)$$

In dilute solutions $V \simeq 55.5\,\bar{V}_{water}$, so that

$$-\delta\Delta\bar{V} = m(V_{salt} - \bar{V}_{salt}) \qquad (7)$$

Any change in $\Delta\bar{U}$ brought about by the presence of ions is likely to be due to weak binding of ions to sites on the dissolved segments, and if a Langmuir-type isotherm[7] is followed we can expect $\delta\Delta\bar{U}$ to be a linear function of m, so that finally we obtain

$$\frac{\delta T_{c,m}}{m} = \frac{(\delta\Delta\bar{U} - P(V_{salt} - \bar{V}_{salt}))}{\Delta\bar{S}} \qquad (8)$$

Figure 1 shows a plot of $\delta T_c/m$ against $V_{salt} - \bar{V}_{salt}$ for the effect of sodium, potassium and ammonium halides on the PVME T_c. With the exception of NH$_4$Br, these salts have approximately constant values of $\delta T_c/m$ up to 1 M concentration. In the case of NH$_4$Br an initial slope was estimated from the curved T_c against salt concentration graph in ref. 2. V_{salt} values were calculated from Pauling ionic radii[8] and

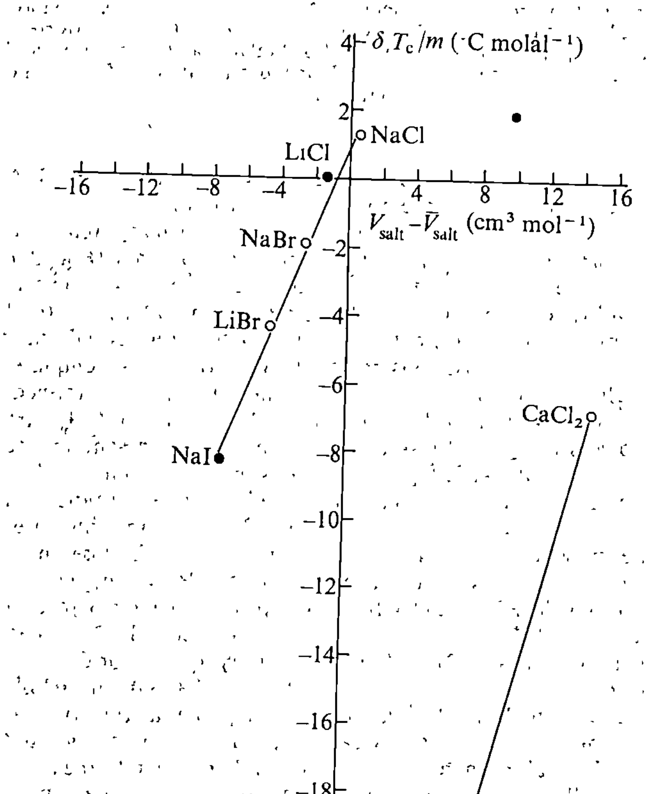

Fig. 2 Salt effects on the thermal denaturation of ribonuclease in aqueous solution. ○, Ref. 3; ●, ref. 4.

$\bar{V}_{\text{salt}}$ values at infinite dilution and 25 °C were taken from a compilation by Millero[9]. The resulting points fall on three parallel lines, one line for each series of anions with a common cation. This justifies the assumption of constant $\Delta\bar{S}$ and implies that $\delta\Delta\bar{V}$ is dictated by both the cation and anion of a particular salt but that $\delta\Delta\bar{U}$ only depends on the cation. The different intercepts on the $\delta T_c/m$ axis may be interpreted in terms of a greater tendency to ion binding in the order $NH_4^+ < K^+ < Na^+$.

Figure 2 shows a similar plot for the effect of seven salts on the ribonuclease transition. A similar picture is obtained except that the lines have positive slopes because the aggregation process is favoured at low temperatures. Lithium and sodium salts give almost the same positive intercept on the $\delta T_m/m$ axis, whereas the calcium salts have a large negative intercept. Bearing in mind that $\Delta\bar{S}$ is now negative, this can be understood on the basis of a relative binding strength for sites on the protein in the order Na^+, $Li^+ < H_2O < Ca^{2+}$. If this interpretation is correct and if this type of plot proves to be general for other ions and macromolecules, the above approach could provide a useful method for separating solvent effects from ion-binding effects. If the interpretation is incorrect, then the interesting empirical observation of common cation lines requires explanation.

Structural order in chromatophore membranes of *Rhodospirillum rubrum*

STRUCTURAL studies of the purple membranes of *Halobacterium halobium*[1–4] have raised the question of whether the in-plane structural order is an exceptional feature of very limited biomembranes or whether it is somewhat more common. We have found that the structural order exists in the chromatophores of *Rhodospirillum rubrum* and *Rhodopseudomonas spheroides* and the outer membranes of *Salmonella typhimurium*, although extension of the order is limited compared with purple membranes. The present paper reports our results concerning the chromatophores of *R. rubrum*.

Chromatophores were prepared from the carotenoid-deficient blue-green mutant (*G-9*) of *R. rubrum* by grinding cells with aluminum oxide[5], a mild treatment used to isolate chromatophores. Oda and Horio[6] have reported that the chromatophores are vesicles with a diameter of 400–800 Å. Our electron microscopic observations have supported their results. According to Kakuno *et al.*[7], the chromatophore membrane consists mainly of proteins and lipids, the weight ratios of protein, phospholipid, bacteriochlorophyll and ubiquinones being 1.00 : 0.24 : 0.04 : 0.03. Major protein components are those which have been termed structural proteins by Kakuno *et al.*[7], and have the molecular weights of 13,000 and 27,000, respectively. The population of the former is about twice the latter (T. Kakuno and T. Horio, personal communication).

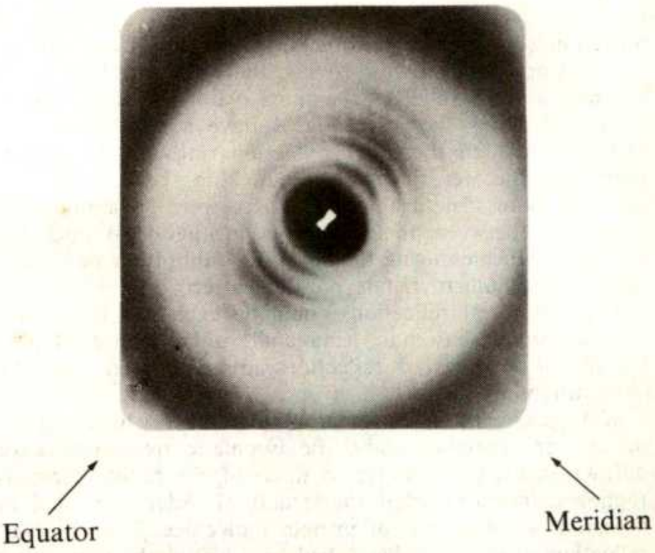

Fig. 1 X-ray diffraction pattern for a dried specimen of chromatophores obtained by grinding cells with aluminium oxide. Specimen-to-film distance 69.3 mm. Exposure time 44 h. See text for equator and meridian.

Pellets of chromatophores were prepared by centrifugation (for example, at 100,000*g* for 1 h). Two kinds of specimens were used for X-ray studies: wet pellets which were a dispersion of chromatophores in the solution of 0.1 M Tris-HCl buffer (*p*H 8.0); and dried specimens which were prepared by placing the wet pellets on a freshly cleaved mica surface, maintained at about 5 °C in a refrigerator for more than 2 d. Strips were then cut off from the dried matter. Each specimen was sealed in a thin-walled glass capillary and its temperature maintained at 4 °C for X-ray exposure. A Rigaku rotating-anode microfocus generator (RU-3HM) was used with a copper target, of which the effective focal spot was 100×100 μm^2. The camera used was of the Elliott point-focusing type[8] with a set of double-sector apertures. X-ray diffraction patterns were recorded on Fuji medical X-ray film KX.

All the wet specimens gave diffraction patterns consisting of a series of distinct diffraction rings in the region of the spacing d of $6\ \text{Å} < d < 22\ \text{Å}$ and a sharp ring at $d = 4.16$ Å, indicating crystalline packing of hydrocarbon chains in the membranes. All the dried specimens gave diffraction patterns as shown in Fig. 1, when the incident beam was parallel to the plane attached to the mica plate. We have termed the direction parallel to this plane equator and the

h, *k*, Miller indices.

perpendicular direction meridian. In Fig. 1 the 4.16Å reflection (clearly seen on the original film) came out as an equatorial reflection, proving that the membranes lie approximately parallel to the mica plate. The inner equatorial reflections shown in Fig. 1 have a one-to-one correspondence with the inner reflection rings on the photographs of the wet specimens, indicating the existence of some in-plane structural order. There were no appreciable differences between their spacings in the dried and wet specimens. In measuring the spacings, calibration was made using the sodium myristate powder pattern.

The equatorial reflections could be explained by assuming a two-dimensional hexagonal unit cell $a=42.6$Å. Calculated spacings of reflections are compared with the observations in Table 1.

Wet specimens of chromatophores from which ubiquinones were removed using the isooctane treatment[9] gave diffraction patterns similar to those of the native chromatophores, indicating that the structural order is related to a regular arrangement of protein molecules. The observed reflections listed in Table 1 had broader widths than those of the purple membranes of *H. halobium* measured with the same camera, implying that the structural order extends only in a limited area of the chromatophore. On the assumption that the protein molecules form small two-dimensional crystalline clusters, the observed line width gave the diameter of the cluster as being about 120Å, roughly three times the lattice constant *a*, on the basis of Scherrer's formula.

Dried specimens gave several meridional reflections as seen in Fig. 1. Six meridional reflections were observed for the native chromatophores and eight for the ubiquinone-deficient chromatophores. In the latter case the eight were indexed approximately by assuming a lamellar stacking of membranes with a period of 155 Å, with reasonable accuracy up to the fourth-order reflection; such an indexing was not successful for the native chromatophores. In addition to these, there was an off-meridional reflection with a spacing of 37 Å in both cases. The lamellar reflections and the period of 155 Å suggest that the chromatophores are flattened in the dried specimens, since a thickness for the membrane of 155 Å/2=76 Å is plausible.

Similar diffraction patterns indicating structural orders have been found in the chromatophores of *Rps. spheroides* and the outer membrane of *S. typhimurium*. A dried specimen of the former also exhibited lamellar reflections as in the case of *R. rubrum*. Further investigations are in progress.

We thank Professor T. Horio for discussions; and Mr G. Soe and Miss K. Sakata for preparation of chromatophores.

Bacterial utilisation of organic matter in the deep sea

DISSOLVED organic carbon (DOC) in the deep sea is, after sedimentary humus, the largest reservoir of organic carbon in the hydrosphere. It is utilised primarily by heterotrophic bacteria, which over a long period, in steady-state conditions consume dissolved O_2 from the seawater and produce an equivalent amount of CO_2 by respiration. Knowledge of the rates of O_2 consumption (Table 1) and CO_2 production is useful for quantifying the mixing and circulation of deep-sea water through variations in its O_2 or natural radiocarbon content[1,2]. The aim of the work reported here was to determine the growth rate of a heterotrophic, low nutrient bacterium isolated from seawater collected at a depth of 2,000 m in the north-central Pacific Ocean (25°03′N, 154°53′W), and to equate this growth rate with O_2 consumption and utilisation of DOC.

We have determined the doubling time in batch culture for this low nutrient bacterium (referred to as 169 and able to grow well in unenriched seawater) in deep-sea water at 5, 13 and 20 °C and under 200 atmospheres of hydrostatic pressure (equivalent to a depth of 2,000 m). The doubling time was 260 h when normalised to the *in situ* temperature of 2 °C using the Arrhenius plot. This growth rate results in a maximum rate of O_2 consumption of 1.4 ml m^{-3} yr^{-1}, and is discussed in terms of the flux of organic and inorganic carbon between various carbon reservoirs in the deep sea.

The equation for determining bacterial respiration in steady-state conditions was

$$R\,(\mathrm{ml\,O_2\,m^{-3}\,yr^{-1}}) = \frac{1.6\times 10^{10} A(100-E)}{D},$$

$$(1\ \mathrm{ml\,O_2\,m^{-3}\,yr^{-1}}) = 0.44\ \mathrm{mg\,C\,m^{-3}\,yr^{-1}}$$

where R is respiration, A is biomass of synthesised microbial cell carbon (g), E is percentage of carbon assimilated, $100-E$ is percentage of carbon respired, and D is doubling time of microbial cells (h). The factor 1.6×10^{10} takes into account the normalisation of doubling times of hours to years, and conversion of g carbon to ml of O_2. A was calculated using the following expression

$$A = 10^{-13} NV$$

where N represents numbers of bacteria per l, V is volume of each bacterium (μm³), and 10^{-13} is the weight of one bacterium of volume 1 μm³ expressed as g of carbon. Each bacterium is assumed to be 80% water and 10% carbon. In our calculations, bacterial volumes were determined from many enumerations of bacteria in deep-sea samples, either by direct microscopy or with the scanning electron microscope (SEM). SEM observations were made on cells fixed *in situ*. We used cell volumes calculated for cocci (0.2 and 0.5 μm diameter) and rods (0.2×0.5 and 0.5×1.0 μm). Numbers of bacteria per l in the central Pacific Ocean deep water were obtained from two sources[4,7], and from our own observations. These values ranged from 10^6 to 10^7 l^{-1}.

The percentage of carbon assimilated (E) in the above equation is difficult to estimate for deep-sea bacteria *in situ*. Most terrestrial heterotrophic bacteria studied in the laboratory in enriched conditions show 10–20% efficiency. Sorokin[4] found that 40% and Jannasch[3] 95% of acetate added to seawater (100 and 2,000 mg l^{-1}, respectively) was assimilated by deep-sea bacterial populations.

To calculate R, we used combinations of the above cell volumes, and assumed that the carbon cycle in the deep sea, including bacteria, is in a steady state (otherwise, there would

Table 1 Utilisation of organic carbon in the deep sea

Method	Depth (km)	Location	DOC and/or POC utilisation (mg C m^{-3} yr^{-1})*
Calculated from a vertical diffusion[1] advection model	1–4	Central Pacific	About 1.8 (4.1)
Calculated from a vertical diffusion[2] advection model	1–4	South Pacific	About 0.67 (1.5)
In situ incubation with ^{14}C-labelled[3] substrates	5	North-east Atlantic	2–13 (4.6–29.6)
In situ incubation with ^{14}C-labelled[4] substrates	4	Western Pacific	11.2–33.6 (25.6–76.7)
O_2 uptake by electron transport[5] system	1–6	Eastern tropical Pacific	About 0.70 (1.6)
Adenosine triphosphate[6] content of cells	1–4	North-east Pacific	About 0.44 (1)
This report	2	North-central Pacific	0.04–0.61 (0.09–1.4)

Calculated and experimental values are given. Equivalent O_2 consumption rates are based on 1.0 ml O_2 consumed = 0.44 mg C utilised, assuming a C/N ratio by atoms of 10 in deep-sea DOC and POC.
*In parentheses: O_2 consumption (ml O_2 m^{-3} yr^{-1}).

be a net increase in biomass); we therefore assumed 100% of DOC to be respired; that is $E = 0$. The range of values for R obtained from these combinations was 0.09–1.4 ml O_2 m^{-3} yr^{-1} (0.04–0.61 mg C m^{-3} yr^{-1}). But from what seems to be the most reasonable assumptions for N and V (3.8×10^6 l^{-1} and 0.26 μm^3 respectively), a value of 1.4 ml O_2 m^{-3} yr^{-1} (0.61 mg C m^{-3} yr^{-1}) for R is the most realistic and represents the upper limit of R. In this calculation we treated all bacteria in the deep sea as growing in a manner similar to that of low nutrient bacteria. This is probably not true; some bacteria may be less, and some more active, than bacterium 169.

Previous *in situ* measurements of bacterial uptake of DOC[3,4] were based on high concentrations of added substrate and so may not be relevant to measurements of the actual activities of deep-sea bacteria. Because little is known of the chemical composition of the DOC in deep water, the estimates for utilisation of DOC we have obtained using the natural substrate are more appropriate for calculating organic carbon fluxes and rates of utilisation of O_2 in the deep sea than rates derived from experimental work with added substrates. The particular fraction of the DOC which is utilised by low nutrient bacteria may be organic material of a more labile nature than the 'old', refractory DOC constituting the bulk of the organic matter, but we cannot judge which fraction is utilised.

This determination of organic carbon utilisation, 0.61 mg C m^{-3} yr^{-1} (1.4 ml O_2 m^{-3} yr^{-1} consumed), may be used in a qualitative way to estimate the organic carbon balance at 2,000 m in the north-central Pacific. If we assume a steady state, ($-dDOC/dt = -dPOC/dt = -dO_2/dt = +dCO_2/dt = 0$), and concentrations of DOC (unpublished results from cruise Cato-1, Institute of Marine Resources, University of California, San Diego, June–July, 1972), POC, particulate organic carbon[8] and O_2 (ref. 9) of 450 mg m^{-3}, 3 mg m^{-3} and 1.7 l m^{-3}, respectively, then the residence time of DOC, POC and O_2 would be 738, 4.9, and 1,214 yr, respectively. This calculated DOC residence time of 738 yr is three to five times lower than the value of 2,600–3,500 yr determined by natural radiocarbon measurements of the DOC at 2,000 m in the north-east Pacific[10,11]. This suggests that R is less than 1.4 ml O_2 m^{-3} yr^{-1} and that the rate of utilisation of DOC is > 0.1 and < 0.5 mg C m^{-3} yr^{-1}. The POC would be utilised in ~ 5 yr if the entire microbial population is using POC and not DOC as a substrate. This is unlikely for two reasons: first, the percentage of attached, non-filterable bacteria compared with the free-living population is 25% or less[7], and second, the consumption of POC by bacteria during the estimated mean time of 2 yr it takes the POC to sink from 500 to 2,000 m (ref. 11) would be 1.22 mg C m^{-3} ($2R$). Such a rate of utilisation would require a gradient (decreasing concentration) of POC from 500 to 2,000 m. This is not observed in the north-central Pacific from 500 m to the bottom, where the concentration of POC is essentially invariant[8]. It thus seems that DOC is the main source of energy for the low nutrient, heterotrophic bacteria in the deep water of the north-central Pacific, and that the rate of utilisation of organic carbon or consumption of O_2 we have measured is of the same magnitude, and probably less, than earlier experimental estimates of a more indirect nature given in Table 1. Indeed, if the rates of O_2 consumption were much greater than 0.6 ml O_2 m^{-3} yr^{-1}, vast areas of the deep sea would be anoxic.

Finally, the results reported here support the validity of using vertical-diffusion, vertical-advection models[1,2] for calculating such non-conservative properties such as O_2 consumption and carbon utilisation in the deep sea.

Circadian rhythm of anaerobiosis in a polychaete annelid

ALTHOUGH intertidal organisms which cannot breathe air must be regularly subjected to tidal conditions in which they must respire anaerobically, there are no known cases in which these or other animals reduce environmental conditions to the point at which they must respire anaerobically. Indeed such reduction of microhabitat conditions would not be expected because of the relative inefficiency of known anaerobic energy-generating pathways. This report describes a rhythm of alternating aerobic and anaerobic metabolism in the polychaete *Nereis virens*. The rhythm is circadian under low intensity constant illumination.

Burrows of *N. virens* are ventilated with undulatory movements of the body which serve to draw well-oxygenated water and food into the burrow. I have conducted long term monitoring of the ventilation rhythms of animals adapted to 10.0-ml synthetic burrows[1]. Individuals have been maintained in synthetic burrows in the laboratory for periods of up to 20 months. Ventilation activity was measured with a directly heated thermistor flowmeter inserted through the wall of the synthetic worm burrow and separated from the animal by a nylon screen[1].

Twelve individuals were tested in continual light (LL 12 : 12), eight individuals were tested in a light–dark regime of 12 h light and 12 h dark (LD 12 : 12), and six individuals were tested in continual darkness (DD 12 :12). A total of 325 d of continuous recording was obtained for the 26 animals tested. Both incadescent and fluorescent light sources were used, and light intensity was maintained at approximately 3,000 lx at the burrow. Before experimentation, all animals (5.0–6.0 g) were maintained on a daily cycle of 14 h light and 10 h darkness at 10±2 °C for 5–70 d. At the start of an experiment individuals in burrows were transferred to a 15-l tank (10 °C) which received a continuous flow of aerated seawater. The thermistor was inserted through the wall of the worm burrow near either end. Vibration and noise from activity in the laboratory were minimised. Several animals were tested in closed as well as open-system conditions to prevent possible influence of chemical time-cues from entering the seawater system.

Ventilation for each hour of each day was measured in relative volume units by determining the areas under the curves of the continuous activity records. Period lengths of ventilation rhythms were estimated using the periodogram procedure of Enright[2] which is particularly appropriate for serially correlated time series data. The experimental amplitudes for a series of computer-generated assumed period lengths are compared; the measure of amplitude is the standard deviation of the hourly means of activity (area under the activity records). The plot of amplitude estimates against the assumed period length is a periodogram, and the period value with a large amplitude represents the most likely correct period length for the observed function. All ventilation rhythms were analysed for likely period lengths from 3 to 33 h in 0.1-h increments.

Burrow $p\text{O}_2$ was monitored continuously with a 1.0-mm polarograph (IBC) during long term ventilation recordings. Burrow *p*H was monitored continuously with a combination microelectrode (Bolab) inserted through the wall. Levels of lactate in burrow water and tissue were determined enzymatically according to the appearance of NADH at 340 nm (ref. 3). In separate experiments groups of six worms were placed in 10-ml sealed burrows and sampled for either tissue lactate or burrow water lactate after a chosen period of forced burrow closure. Respiratory rates were determined separately for 22 individuals placed in air-saturated seawater (10 °C), after various periods of forced closure in 10-ml synthetic burrows.

While I have observed short term (3–20 min) cycling of ventilation and rest periods similar to those observed for other polychaetes[4–9], I have also observed longer rest periods (>1 h) superimposed on the short term irregular pattern. These long rest periods (up to 9 h) create anaerobic burrow conditions and appear in recordings only after 2–4 d. In conditions of constant illumination, the ventilation activity shows a circadian periodicity (Fig. 1*a* and *b*). While one of 12 animals tested in LL was aperiodic, the average observed period length was 21.3±s.d. 0.65 h and the average duration of rest periods >1 h was 3.85±2.4 h. While all animals tested in LD and DD were aperiodic (Fig. 1*c*–*f*),

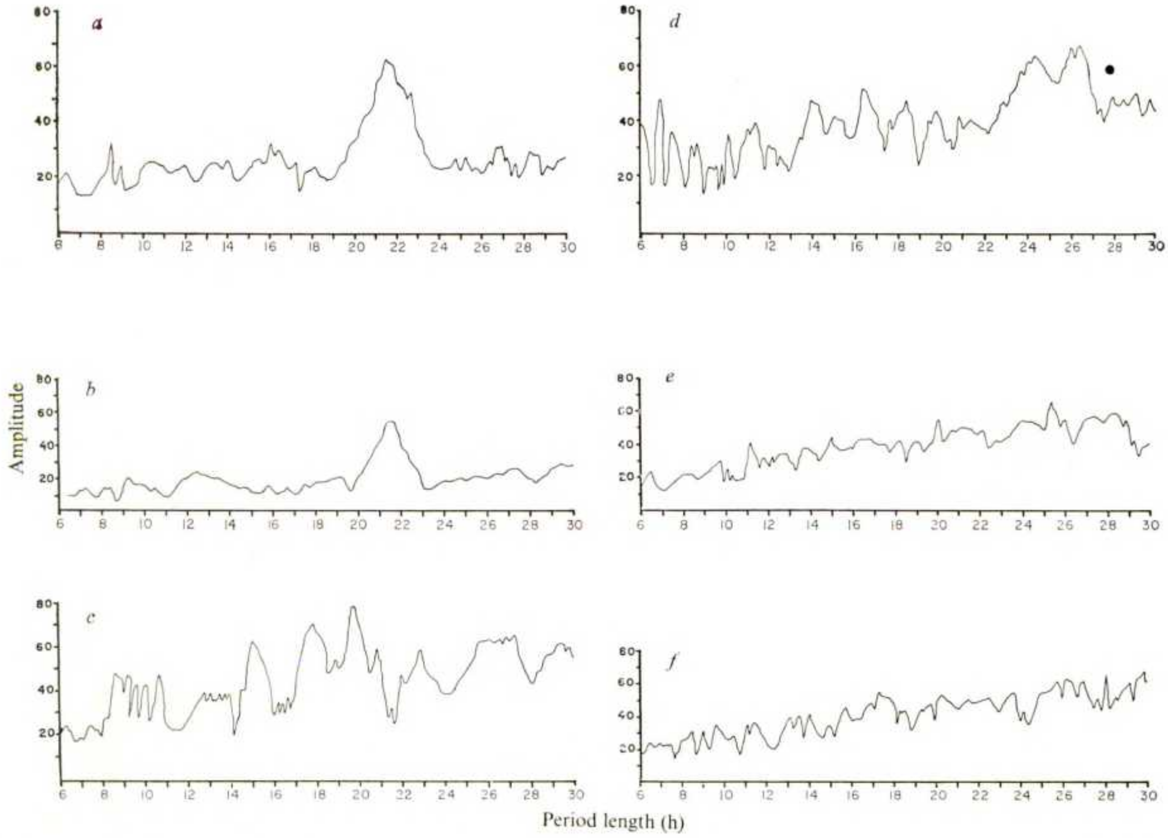

Fig. 1 Typical periodograms of burrow ventilation. *a*, *b*, Periodic anaerobiosis under constant illumination; *c*, *d*, aperiodic activity under light–dark cycle; *e*, *f*, aperiodic activity in constant darkness.

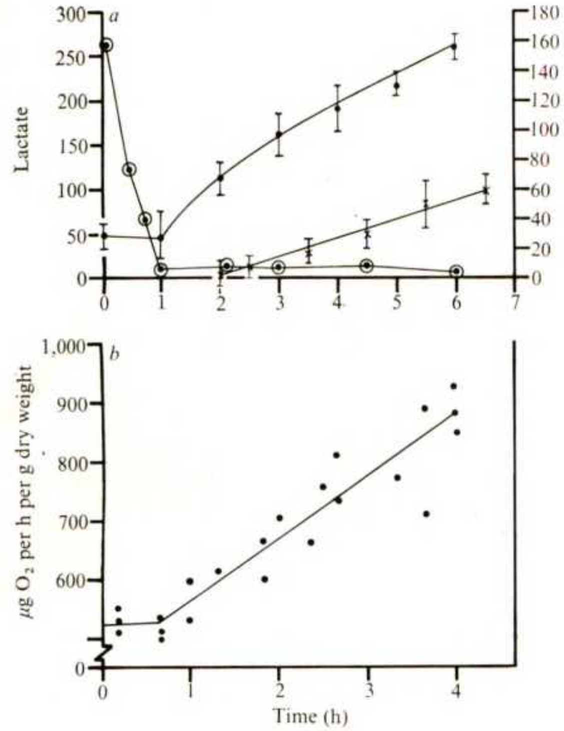

Fig. 2 *a*, Tissue lactate (●, μg per g wet tissue ± s.e., $n = 6$), burrow lactate (×, μg per ml burrow water ± s.e., $n = 6$), and pO_2 (circle and dot) as a function of length of rest period ($n = 8$). *b*, Maximum oxygen consumption following various lengths of rest periods ($n = 22$). Tissue lactate, burrow lactate and respiratory debt were determined for groups of six animals placed in sealed 10-ml burrows (10 °C) for predetermined times, since it was impractical to obtain tissue or water samples during the rest periods observed in the ventilation studies. The *p*H records obtained from burrows during spontaneous rest periods of the ventilation studies agree closely with those obtained at the end of the forced-closure experiments.

long rest periods were nevertheless observed in both of the latter conditions. The average lengths of rest periods >1 h in the LD and DD groups were 3.39 ± 1.45 and 3.13 ± 2.0 h, respectively. The frequencies of occurrence of rest periods >1 h varied for animals tested in LL, LD and DD and were 1.15 ± 0.21, 0.60 ± 0.14 and 0.52 ± 0.10 per d, respectively. Furthermore, the DD group spent an average of 71% of each day involved in ventilation activity while the LL and LD groups averaged 21 and 35%, respectively.

Measurements of oxygen consumption, lactate and *p*H within the polychaete burrow indicate that during rest periods, the worms respire anaerobically, accumulate small amounts of lactic acid and later pay an oxygen debt.

At a burrow oxygen tension of 5–10 mmHg (10 °C), detectable aerobic respiration ceased and presumably there was a switch to anaerobic pathways. Lactate appeared in the sealed burrow after a 2-h rest period and reached 92 $\mu g\,ml^{-1}$ after 6.5 h (Fig. 2*a*). Increased tissue lactate levels were evident after about 1 h, which is approximately the time required to reduce the burrow pO_2 to 5–10 mmHg, and reached approximately 260 μg per g wet tissue after 6 h. When a rest period ended and the burrow was again ventilated, the oxygen debt was repaid in part, as indicated by increased respiratory rates (Fig. 2*b*), which were directly related to the length of the period of forced closure.

Continuous monitoring of burrow *p*H during ventilation studies showed that burrow acidity was a function of the length of the rest period, with *p*H on one occasion reaching a low value of 5.97 after 8.2 h of rest. Organic acids other than carbonic and lactic must account for such observed depressions in *p*H because, in theory, *p*H could be reduced only from 8.1 to about 7.0 by animal respiration.

In summary, *N. virens* seems to cease burrow ventilation for periods of up to 9 h during which respiration continues anaerobically and the worms accumulate lactic and other organic acids. It is doubtful that the vascular haemoglobin serves an oxygen storage function during extended tidal exposure[5].

Newell[10] has suggested that temperature-independent resting metabolism (O_2 consumption) is associated more often with animals found intertidally than with those found subtidally, although two polychaete species have resting metabolic rates that are temperature dependent[11]. The observation of a spontaneous creation of anaerobic burrow conditions is important since normal rest metabolism of many invertebrates may include a significant non-oxidative component involving accumulation of lactate or other partially oxidised products of the Embden–Meyerhoff pathway. Any function of the observed periods of anaerobiosis, as well as the role of low intensity illumination in synchronising the anaerobic periods is as yet unknown.

It is interesting that the bivalve *Arctica islandica* has been shown to burrow aperiodically into sediments and respire anaerobically[12].

I thank A. H. Price, II and S. Kraul for review of the manuscript. This work was supported in part by NOAA Office of Sea Grant.

Plutonium isotope ratios in polychaete worms

WE have noted with interest recent reports which suggest a preferential biological availability of ^{238}Pu over $^{239+240}$Pu in terrestrial and aquatic organisms[1–4]. Although kinetic isotope effects do occur in biological systems for low mass number elements (H, C, N), such effects are generally discounted as the mass number of the element increases. Thus, differential biological availability of isotopes of high mass number elements, such as plutonium, would normally be attributed to differences in the chemical or physical forms of the isotopes or to the different weights of isotope available to organisms as a result of large differences in their specific activities. These arguments have indeed been used to explain differential plutonium isotope behaviour in animals in controlled laboratory conditions[5–7]. It is not certain, however, that the same arguments can be used to explain anomalies of plutonium isotope behaviour in organisms contaminated by nuclear test debris or by wastes from nuclear fuel reprocessing plants. Plutonium activity levels, while easily measurable, do not approach those generally used in laboratory studies. In addition, geochemical weathering could conceivably alter any original differences in physical or chemical form of the plutonium. We report here the results of experiments which show that deposit-feeding marine worms living in sediments contaminated with plutonium isotopes in different ways do not preferentially accumulate ^{238}Pu over $^{239+240}$Pu. This is particularly significant in that the worms held in sediments contaminated in the natural environment may have been exposed to different chemical and physical forms of plutonium isotopes.

Table 1 Plutonium isotope ratios in polychaete worms and sediment

Sediment sample	Mean ^{238}Pu/$^{239+240}$Pu ratios	
	Worms	Sediment
Mediterranean	0.0076 ± 0.0030 (4)	0.0082 ± 0.0006 (5)
Bravo Crater	0.10 ± 0.02 (4)	0.082 ± 0.004 (5)
Windscale	0.25 ± 0.04 (3)	0.231 ± 0.004 (4)

Errors associated with the ratios are propagated at the 2σ confidence interval. Numbers in parentheses indicate number of samples used in calculating mean ratio.

We exposed polychaete worms (*Nereis diversicolor*) to laboratory-labelled sediment, sediment collected from a former weapons test site and sediment contaminated by wastes from a nuclear fuel reprocessing plant, in an attempt to observe any preferential uptake of ^{238}Pu over $^{239+240}$Pu. To prepare our laboratory-labelled sediment, we added 91 nCi of $^{239+240}$Pu (containing trace amounts of ^{238}Pu) in either the +4 or +6 oxidation state to 1 l of Millipore-filtered (0.45 µm) Mediterranean seawater with constant stirring. Some 200 ml of Mediterranean sediment was then introduced into the seawater and the slurry was allowed to mix for 2 d. After settling, the seawater was decanted and several fresh seawater washes were performed to remove any plutonium not bound to the sediments. A portion of a core sample (23–49 cm deep) collected from Bravo Crater at Bikini atoll and several hundred grams of surface sediment collected from the Irish Sea near the Windscale fuels reprocessing plant on the Cumbrian coast were equilibrated for several days with filtered Mediterranean seawater in a manner identical to that of our laboratory-labelled sediment. Aliquots of all sediment samples had easily measurable quantities of ^{238}Pu and $^{239+240}$Pu ($\sim 2\times10^4\times$ higher than fallout levels in coastal ocean sediments for the lowest activity sample) and homogeneity was good. Since the Bravo Crater sediment was contaminated as the result of testing a large thermonuclear device (1954) we tested the homogeneity of plutonium isotopes further by leaching an aliquot of the sample with a dilute solution of EDTA at *p*H 3 and determined the ^{238}Pu/$^{239+240}$Pu ratio in portions of the leachate with time. No differences in isotope ratios were observed, suggesting that both small and large particles of the sediment were homogeneous with respect to both isotopes.

Worms introduced into the sediments were allowed to accumulate plutonium for between 5 and 40 d. At prescribed times during this interval, 5 to 31 individuals were removed from the sediments, rinsed several times in clean seawater and placed in uncontaminated Mediterranean sediments for 24 h, where they were allowed to void their gut contents by ingesting sediment. Finally, all sediment was removed from the organisms by placing them on a mat of wet algae for a further 24 h. Radiochemical analyses of both worms and sediment were accomplished by standard techniques[9] designed to ensure the radiochemical purity of the separated plutonium. Isotope ratios were determined by α-spectrometric techniques.

Table 1 sets out the results of the isotope ratios observed in the worms and the sediments to which they were exposed. Since no significant differences in isotope ratios were observed in worms killed at different times (5, 9, 15, 25, 40 d), we have averaged all results for each sediment type. The somewhat unsatisfyingly large error terms associated with the Mediterranean and Bikini worm samples result from the extremely low levels of plutonium ultimately taken up by these organisms[9] and the low initial ^{238}Pu/$^{239+240}$Pu ratio in the sediments. Counting times for many samples approached 10 d.

Our results indicate that at least for the polychaete worms studied, no preferential uptake of ^{238}Pu over $^{239+240}$Pu occurs whether the sediment is labelled with known chemical forms of plutonium or whether the sediments contain plutonium from aged nuclear test debris or plutonium from fuel reprocessing wastes. This is in contrast to the near twofold magnification of ^{238}Pu over $^{239+240}$Pu observed between plants and organisms with respect to sediment in a freshwater ecosystem contaminated by nuclear fuel processing wastes[4] and the near 20-fold magnification observed between rodent tissue and soil in a terrestrial landscape contaminated by fallout[2]. Although the reasons for these disparities await clarification, general statements regarding preferential bioavailability of ^{238}Pu over $^{239+240}$Pu after its introduction into different ecosystems should be viewed cautiously. It is moreover worth emphasising that naturally occurring α-emitting radionuclides can follow plutonium in any radiochemical separation scheme, and unless scrupulous attention is paid to the radiochemical purity of the plutonium isolation technique, erroneous values for ^{238}Pu can result[8]. Clearly, such considerations become important for environmental samples where plutonium activity levels are low.

We thank N. Mitchell and F. Lowman for samples and V. T. Bowen for suggesting the EDTA leach experiment. Occurrence of plutonium and americium in plaice from the north-eastern Irish Sea

SMALL amounts of transuranic nuclides are discharged routinely into the north-eastern Irish Sea from the nuclear fuel element reprocessing plant at Windscale, Cumbria. Regular monitoring of the marine environment, as part of the established control procedure is made by the Ministry of Agriculture, Fisheries and Food[1,2], primarily to ensure the radiological safety of the discharges in public health terms. Data on the partitioning of plutonium and americium between seawater, suspended material and sediment have already been published[2,3] and the purpose of this communication is to present a preliminary report of these radionuclides in the plaice (*Pleuronectes platessa*). This is a demersal fish of commercial importance in the area and the critical material for discharges of transuranic nuclides. There are few published data on the concentrations of plutonium in marine fish[4] and no data for americium have been reported.

During 1975 four catches of plaice were made approximately 5 km south of the pipeline. Thirty fish—principally group III, 25–30 cm long—were selected from each catch and their dissected organs were bulked and ashed. Analysis for the plutonium isotopes was based on the method of Wong[5] except that concentration was obtained initially by coprecipitation on calcium oxalate and subsequently on neodymium hydroxide. Separation of americium from plutonium, and purification of the latter, was effected by anion exchange from a hydrochloric acid medium. The americium was separated from lanthanides by anion exchange at 80 °C using ammonium thiocyanate. Both

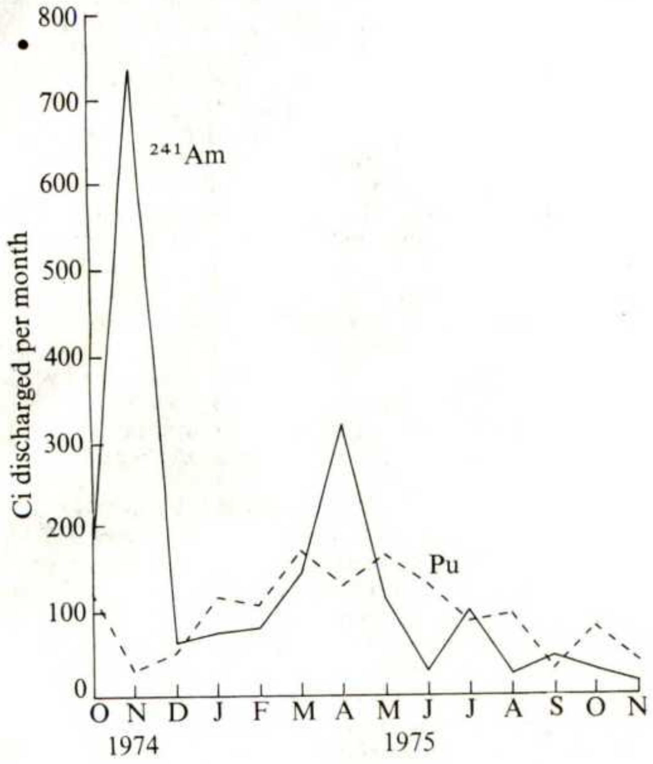

Fig. 1 Monthly discharges of ^{238}Pu, ^{239}Pu, ^{240}Pu and ^{241}Am from Windscale for the period October 1974–November 1975 (from returns made by British Nuclear Fuels Ltd).

plutonium and americium were electrodeposited from a slightly acid ammonium sulphate medium on to stainless steel disks. Radionuclide content was measured by α spectrometry using a 128-channel pulse height analyser and a silicon surface barrier detector (100 mm^2) to ensure adequate separation of the isotopes from the yield tracers ^{236}Pu and ^{243}Am. Chemical recoveries were > 70%. The results, ±2σ counting error, are given in Tables 1 and 2•

The highest concentration of plutonium in the internal organs of the fish collected in February was in the kidneys. Concentrations in the kidneys of fish caught later in the year, however, were exceeded by those in the gut. Plaice feed little during the winter and most of those caught in February were void of gut contents. The other three samples all contained various food species, consisting largely of *Amphiura filiformis*, which was particularly dominant in the sample collected in May, and several lamellibranchs including *Ensis ensis*, *Abra alba*, *Cultellus pellucidus* and *Nucula turgida*. Less frequent were *Nephthys*, *Pectinaria* and *Aphrodite*. The predominance of these species suggests that the fish had been feeding in an area of muddy sand, and not inshore of the pipeline[6]. It is interesting that although during the summer the food intake was greatly increased, and the discharges of plutonium were somewhat higher during the early summer (Fig. 1), neither the concentration of plutonium in the liver, nor that in the muscle, increased significantly. The concentrations in the gut wall, although higher in the samples taken after February, were about two orders of magnitude lower than the gut contents. Concentration by the gill was highest in the samples collected in May and August, although external contamination may have been variable in spite of their being well rinsed in clean water during dissection.

Table 2 ^{241}Am in organs of the plaice

Organ	Date of sample collection February 18, 1975	May 13, 1975	August 12, 1975	November 11, 1975
Kidney	440±50	103±15	65±5	120±14
Liver	590±120	186±29	35±6	54±6
Gut	160±20	89±14	114±22	122±17
Gut contents	930±600	6,600±540	4,940±270	7,390±36
Gill	210±60	128±23	310±40	89±7
Skin	20±8	15±2	6.2±2.8	11±0.9
Bone	110±50	33±9	28±6	2.1±0.5
Muscle	2.3±0.5	1.4±0.2	0.9±0.2	0.3±0.08

Results are expressed in fCi per g wet weight.

The concentrations of ^{241}Am in the internal organs were all generally higher than those of plutonium, the ratios being somewhat higher than those of the gut contents for May, August and November. The ^{241}Am data are also interesting in that the concentrations in kidney, liver, muscle and bone decreased markedly from February to August and may well have been influenced by the relatively large release during November 1974 (Fig. 1). It is not certain, however, that the fish sampled during the year have been taken from the same population.

Sufficient material was obtained from the fish in November to analyse gonad tissue. The bulked testis sample contained 0.64±0.3 fCi per g wet weight $^{239+240}$Pu and < 0.5 fCi per g wet weight ^{241}Am. In contrast, the ovaries contained 1.5±0.5 fCi per g wet weight $^{239+240}$Pu and 9.3±3.2 fCi per g wet weight ^{241}Am.

In view of the fluctuating discharges (Fig. 1) it is evident that a steady-state body burden will not exist for fish caught close to the pipeline. An accurate estimation of a concentration factor over seawater therefore cannot be made, and would in any case depend on the location of the seawater sample and the movements of the local population of plaice. Seawater samples were taken from the area fished during July 1975 and contained ≈1 pCi l^{-1} of $^{239+240}$Pu and ≈0.2 pCi l^{-1} of ^{241}Am in the filtrate (< 0.22 μm) (personal communication from D. F. Jefferies). Thus the approximate concentration factors over seawater (filtrate) for the samples of muscle collected in August are of the order of < 1 for $^{238+239}$Pu and ≈5 for ^{241}Am. The data obtained also emphasise the very low levels of plutonium and americium in the edible fraction of Irish Sea plaice taken from the area most liable to contamination; the concentrations measured in fish muscle are equivalent to less than 0.01% of

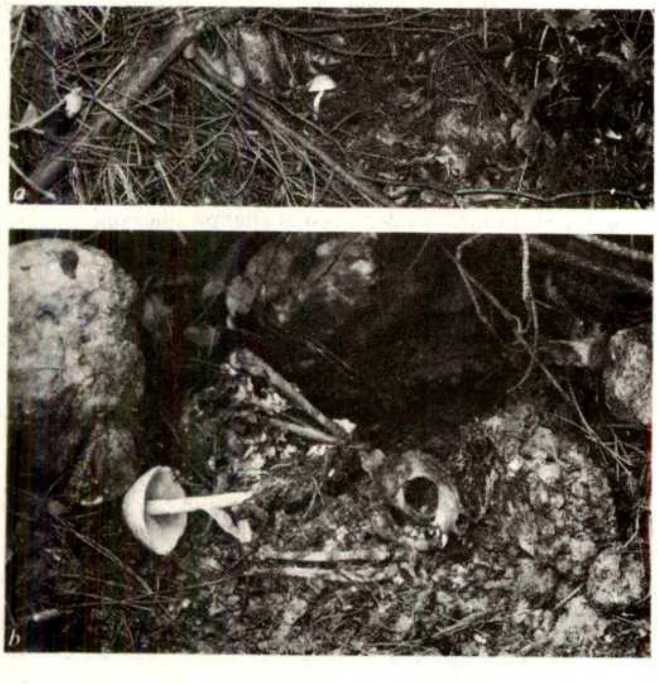
Presence of a buried mammalian carcass indicated by fungal fruiting bodies

Hebeloma vinosophyllum Hongo is a terrestrial agaric originally found in broad-leaved and conifer forests but not described as having any special ecological requirements[1]. It now seems that this species often fruits where a dead mammal has been buried.

On August 24, 1968 I found a group of luxurious fruiting bodies of this species in a stand of *Castanopsis cuspidata* at Iwakura, Kyoto. The fruiting bodies appeared to be well nourished and covered an area of about 1,500 cm². The surface of the ground did not seem to have been disturbed. This fungus had been found to fruit well only when the ground in forests has been dressed with urea or a similar material which releases ammonia on decomposition[2]. The presence of fruiting bodies in an untreated area suggested that there might have been a source of nitrogen in the soil. At a depth of less than 10 cm I found the remains of a dog carcass, which consisted of bones and decayed skin, and the soil around the carcass contained abundant white mycelia.

Fig. 1 *a*, Fruiting body of *H. vinosophyllum* on the superficially normal ground. *b*, Fruiting body together with cat bones taken from soil under that fruiting body.



On October 8, 1975 a single well developed fruiting body of the same species was found in a stand of *Pinus densiflora* at Yoshida-yama near the Kyoto University campus. As before, the ground appeared to be superficially normal but some pieces of cat bone were found in the top 20 cm of soil. The soil and bones were replaced and on October 30 another fruiting body appeared (Fig. 1*a*). The bones were removed from the soil and are shown in Fig. 1*b*. On this occasion denatured fatty tissue was found and there was a smell of decaying animal matter. As before, no flesh remained and the soil was whitish with mycelia. In May to June 1976, several fruiting bodies appeared again on the same spot.

These facts do not exclude the possibility that this species colonises normal (untreated) soils. It is often very difficult, however, to determine whether or not a soil is really normal, since human urine and faeces, which also yield this fungus, leave nothing after decomposition. It is well known that entomogenous fungi or caterpillar fungi occur directly on the bodies of some invertebrates but there are no reports of indirect (soil-mediated) occurrences of agarics on mammals. The present finding may lead to speculation that a victim of homicide buried in soil could be located using the fruiting bodies of this or some other fungi, assuming the burial was shallow. (In forensic medicine, 'filamentous fungi' or 'fungal hyphae' are known to occur sometimes directly on human corpses or in graves[3].) After urea or ammonia application this species appears after 3–8 months and continues to fruit over a period of 1–2 yr, forming part of a succession, all the members of which respond to this treatment, and are called ammonia fungi[2]. It is not known whether this species could be used to determine how long a corpse has been buried.

The closely related species *Hebeloma sarcophyllum* Peck (=*H. porphyrosporum* R. Maire) is found in Europe, North Africa and North America[4]. It would be interesting to know if this species has similar ecological requirements.

I thank Dr R. F. O. Kemp, University of Edinburgh, for reading the manuscript.

Appetitive learning, patterned alternation, and extinction in 10-d-old rats with non-lactating suckling as reward

HUGHLINGS-JACKSON[1] has expressed the view that, during ontogenesis, neural centres responsible for inhibition develop more slowly than centres responsible for excitation. Since then, the working hypothesis has been that the later-developing, phylogenetically 'higher' neural centres act to regulate (inhibit?) the excitation of the 'lower' centres. There has been some behavioural and physiological support for this position. In altricial mammalian species the hippocampus and neocortex become functionally mature relatively late in development[2], and the hippocampus, in particular, has been implicated in the expression of behavioural inhibition[3-5] Preweanling rats, during weeks 3 and 4 of life, seem to lack maturity for tasks requiring suppression of responding; for example, they are deficient in passive avoidance[6] learning and in habituating to novel stimuli[7,8] Their performance in excitatory tasks, such as active avoidance[9] and approach for food[10], seems to be less deficient. These task-specific deficits resemble those shown in hippocampally lesioned adult animals[11]. Campbell *et al.* have noted the correspondence between later-developing inhibitory centres in the rat and the decline in spontaneous activity occurring during ontogenesis[12], and have demonstrated that psychopharmacological agents[13] and brain lesions[14] specific to inhibitory systems are ineffective in increasing behavioural arousal early in development. In our laboratory, experiments on instrumental appetitive learning in preweanling rats have involved the use of dry food pellets as reinforcers in pups as young as 17 to 20 d of age. In animals as young as this, we have demonstrated acquisition, extinction, immediate persistence, and long term persistence using procedures that are similar to those for adult rats[15-17]. We now report two experiments demonstrating behavioural plasticity in the 10-d-old rat, involving acquisition and subsequent extinction of an approach response where reward is the opportunity to suck briefly from an anaesthetised mother rat.

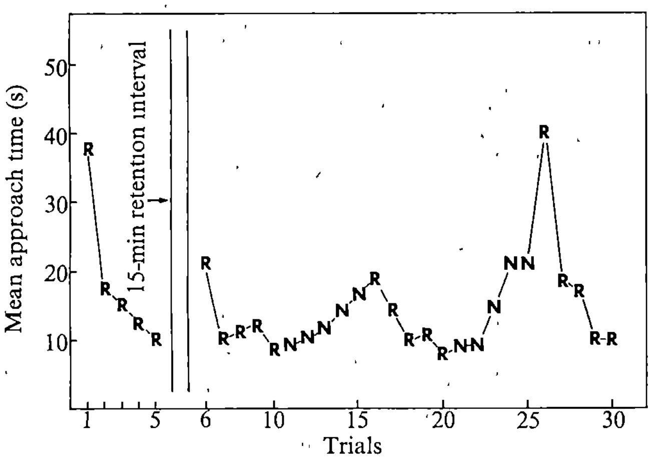

Fig. 1 Mean approach time for animals in experiment 1.

Our first experiment established that infant rats will quickly learn to approach when the reward is an opportunity to attach to a nipple of an anaesthetised mother rat for a brief interval, and that this learned tendency to approach can be successively weakened and strengthened by making the mother inaccessible and accessible on alternating blocks of trials. Our second experiment provided data from acquisition and extinction for two groups of subjects which differed in their schedule of reward in acquisition. The general procedure in both experiments, including deprivation treatment, was as follows: On the morning of day 10 pups from litters culled to 8 at birth were separated from their mother 8 h before training by being placed in a Plexiglas chamber partially filled with pine shavings. Temperature in the chamber was maintained at 37 °C (the average temperature in an undisturbed nest) using thermostatically controlled commercial heating pads placed under the Plexiglas floor. Experimental training was conducted in a clear Plexiglas alley (32 cm long and 8 cm wide) also maintained at 37 °C. Approximately 20 min before the first trial, the mother received intraperitoneally a 2 ml kg^{-1} injection of EquiThesin, a general anaesthetic producing a surgical level of anaesthesia and blocking milk release.

Preliminary training in both experiments consisted of placing each pup separately against the mother and allowing it to attach to a nipple for 15 s. At the end of this interval the pup was gently detached from the nipple, carried by hand to the opposite end of the alley, and placed facing away from the mother. On reward (R) trials the mother was positioned on her side at the end of the alley and the pup was permitted to attach to a nipple for 15 s On non-reward (N) trials the mother was removed from the alley and the pup was picked up when it reached the end of the alley. Time to the nearest 0 01 s for the pup to reach the end of the alley on each trial was recorded. In experiment 1 ($n=5$) preliminary training was followed by 5 massed (3-s intertrial interval) R trials, a 15-min retention interval during which the pup was returned to the deprivation chamber, and 25 massed trials in which R and N trials alternated (ALT) in blocks of 5 trials, starting and terminating with 5 R trials. In experiment 2 the initial 5 R trials and the retention interval were not included and two groups ($n=6$ each) were formed a 5-trial ALT group (as in the last 25 trials of experiment 1), and a group designated continuous reward (CR). Group CR was rewarded on every trial in the acquisition phase by access to a nipple for 15 s. A 10-trial extinction phase began, without signal, immediately after the last acquisition trial. Pups meeting an extinction criterion of 100 s on any trial were terminated and assigned a nominal latency of 100 for all remaining trials.

The results of experiment 1 are shown in Fig. 1. Approach time decreased sytematically over the first 5 R trials ($P<0.05$). After the retention interval, 'savings' was reflected in the first 5 R trials of the ALT phase, the block and block-by-trials interaction effects were both significant ($P<0.05$). This was the first clear evidence of which we were aware of systematic acquisition of an instrumental appetitive response and savings in reacquistion in rat pups as young as 10 d of age. There is also a systematic influence on approach times of alternating blocks of R and N trials across the 25 trials after the retention interval approach times decrease and increase, respectively, in the R and N blocks ($P<0.01$).

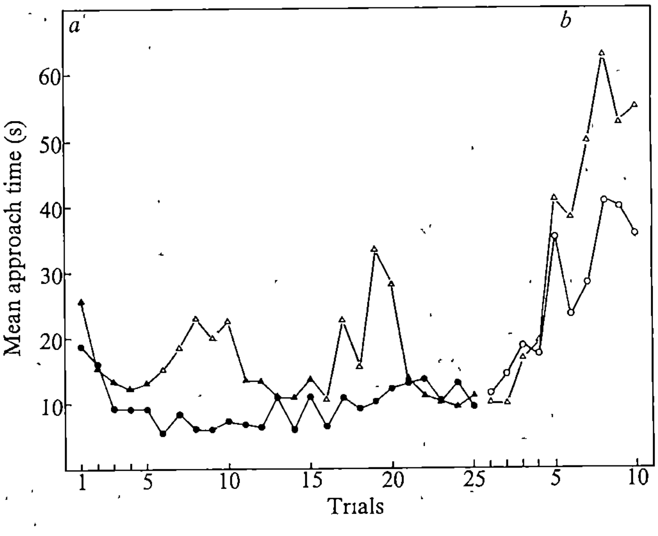

Fig. 2 Mean approach latencies in acquisition (*a*) and extinction (*b*) for the two groups in experiment 2. △, ▲, ALT; ●, ○, CR; ▲, ●, R; △, ○, N.

Figure 2 depicts mean approach latencies in acquisition and extinction for the two groups in experiment 2. Acquisition performance of the ALT group again reflected a behavioural sensitivity to 5-trial blocks of R and N trials. No such patterning was apparent in the CR group, where there was systematic reduction in approach time characteristic of learning across acquisition trials. Both groups showed clear extinction of approach behaviour with successive non-rewards ($P<0.01$). The tendency for the ALT group to extinguish at a faster rate than CR may reflect an extension of the successive 'extinctions' in acquisition.

These results implicate contact with the mother and/or sucking on a dry nipple as sufficient reinforcing events to establish and maintain approach behaviour in 10-d-old rats. Puerperal females under a general anaesthetic, within the range of dosages we used, do not demonstrate normal patterns of milk release from the nipple, and rarely release milk when stimulated by the sucking of a single pup[18]. We have not observed the characteristic milk-ingestion reflex in the pup while it was attached to a nipple of an anaesthetised mother, and we did not find an increase in body weight between pretraining and the end of training. It is therefore unlikely that the pups obtained milk during the brief nursing episodes. If the pups did not receive milk, some other feature(s) of the contact–suckling episodes must have served as the reinforcing stimulus. But to attribute reinforcing properties to contact–suckling we must rule out any distance cues—for example, odour and visual—as factors that strengthen and weaken the approach response. Visual cues are ruled out because the eyes of 10-d-old rats are not yet open, but the extent to which rats of this age can use odour cues is not clear. In the presence of a maternal odour, spontaneous activity in 10-d-old rats is reduced[19]. Rats as young as 12 d of age, but not younger, prefer shavings from home cages to clean wood shavings, presumably on the basis of odour[20]. On the other hand, 10-d-old pups given a choice between their own mother and a nulliparous female show virtually no tendency to approach either one; and the lactating female does not begin to emit the maternal pheromone until about 14 d *post partum,* which is the age at which the young are first responsive to the pheromone[21]. In our own data, there is nothing to suggest that odour cues are the basis for differential responding on R and N trials. Odour cues cannot account for the extinction differences between the two groups found in experiment 2 because both groups were run in identical conditions in this phase. These extinction differences may reflect an associative factor which develops differentially in the two groups in acquisition. As a final check on the involvement of odour cues in our experiments, we have replicated the basic finding of experiment 1 (ALT condition) using a procedure in which the anaesthetised mother is present on all trials at the end of the alley. The mother rat is behind a barrier which is raised on R trials after the pup reaches the goal box, but not on N trials. This procedure rules out the possibility that distance cues emanating from the mother on R but not on N trials control the patterned responding in the ALT group.

These results suggest that the development of forebrain structures in the rat during weeks 3 and 4 of life may not be essential for at least certain kinds of learned response suppression. In our experiments appetitive extinction, suppression of approach in the absence of the mother, reflects an 'inhibitory' effect in rats at 10 d of age; in experiments using electric shock, suppression of approach responses in rats shows up much later in development. Although the concept of inhibition has been applied in a variety of contexts, it has always lacked precise definition in psychology[22], and psychologists, physiologists and biochemists explain a number of disparate phenomena with the term 'inhibition'. Our results demonstrate that the infant rat can learn to anticipate the absence of a previously present appetitive event at an age before recognised inhibitory neural centres are said to be operating.

Models and statistics for species diversity

INTEREST in the pattern of species abundances in a population takes two forms. On the one hand a study of the full distribution of the relative abundances of species may be sought to give insight into the internal mechanisms of the community; in other cases one or more summary statistics which suitably characterise the population may be required to investigate effects of evolutionary or environmental change. The first approach has led

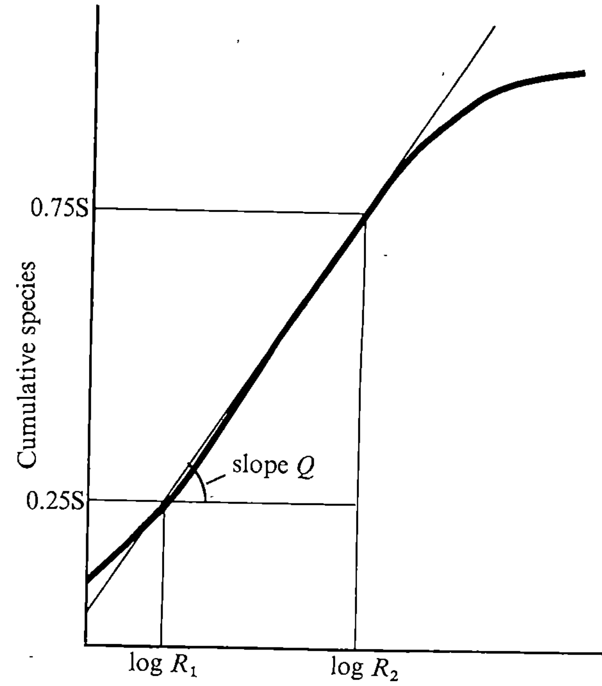

Fig. 1 Evaluation of quantile statistic, Q, from cumulative species abundance curve.

Table 1 Analysis of variance of diversity statistics for 7 replicate samples of moth catches from light traps at 14 sites in the Rothamsted Insect Survey

Source of variation	d.f.	Variance mean square			
		Simpson	H	Q	α
Between sites	13	0.00174	0.977	832.4	1037.5
Within sites	78	0.00014	0.018	6.4	6.4
Between to within sites variance ratio		12.1	54.0	130.5	163.1

Ability of the statistics to discriminate between sites is indicated by the size of the variance ratio, between to within sites.

α, Diversity parameter of the log-series.

to much argument over the appropriate mathematical form for the distribution of abundances, often in the belief that the acceptance of a particular mathematical model will tell us something about the causal biological mechanism. In our opinion, however, the primary purpose of fitting a mathematical model is to smooth the data and enable efficient estimation of population statistics from the parameters of the model; for this we would choose the simplest model which adequately describes the data. Further, there are clear advantages in fitting a single model to describe a series of sets of data—even if this model does not give the best fit to each one—rather than fitting several different models, as has often been suggested, particularly in the literature on succession.

The use of a single diversity statistic to summarise the full distribution of the relative abundances of species has obvious appeal, in spite of recent criticism of many statistics in common use. Here again we would make no pretence at functional modelling but suggest that species diversity is most usefully regarded as a descriptive statistic for multispecies populations of the same type as, say, population density. Like average density, it is best represented by a statistic that does not overemphasise the commonest or the rarest species, particularly as species frequency distributions are usually very long tailed. We have strongly criticised[1] the two diversity statistics in common use, the information statistic (H) and Simpson's index, because of their sensitivity to the few commonest species, the numbers of which we have found to fluctuate erratically from year to year, rather than to those more stable species with medium abundance.

An alternative diversity index which does not suffer from these disadvantages is based on the slope of the cumulative species curve in the mid-range of abundances (Fig. 1). Mathematically we define

$$Q = S/2 \log(R_2/R_1)$$

where S is the total number of species in the sample and R_1 and R_2 are the lower and upper quartiles of the species abundance distribution (see ref. 2, p. 226). Clearly, Q is much less sensitive to the commonest species in the sample, than H or Simpson's index, and we have found that it shows smaller relative variability between years and discriminates better between different sites (Table 1).

Fitting a model to the data enables the diversity statistics to be

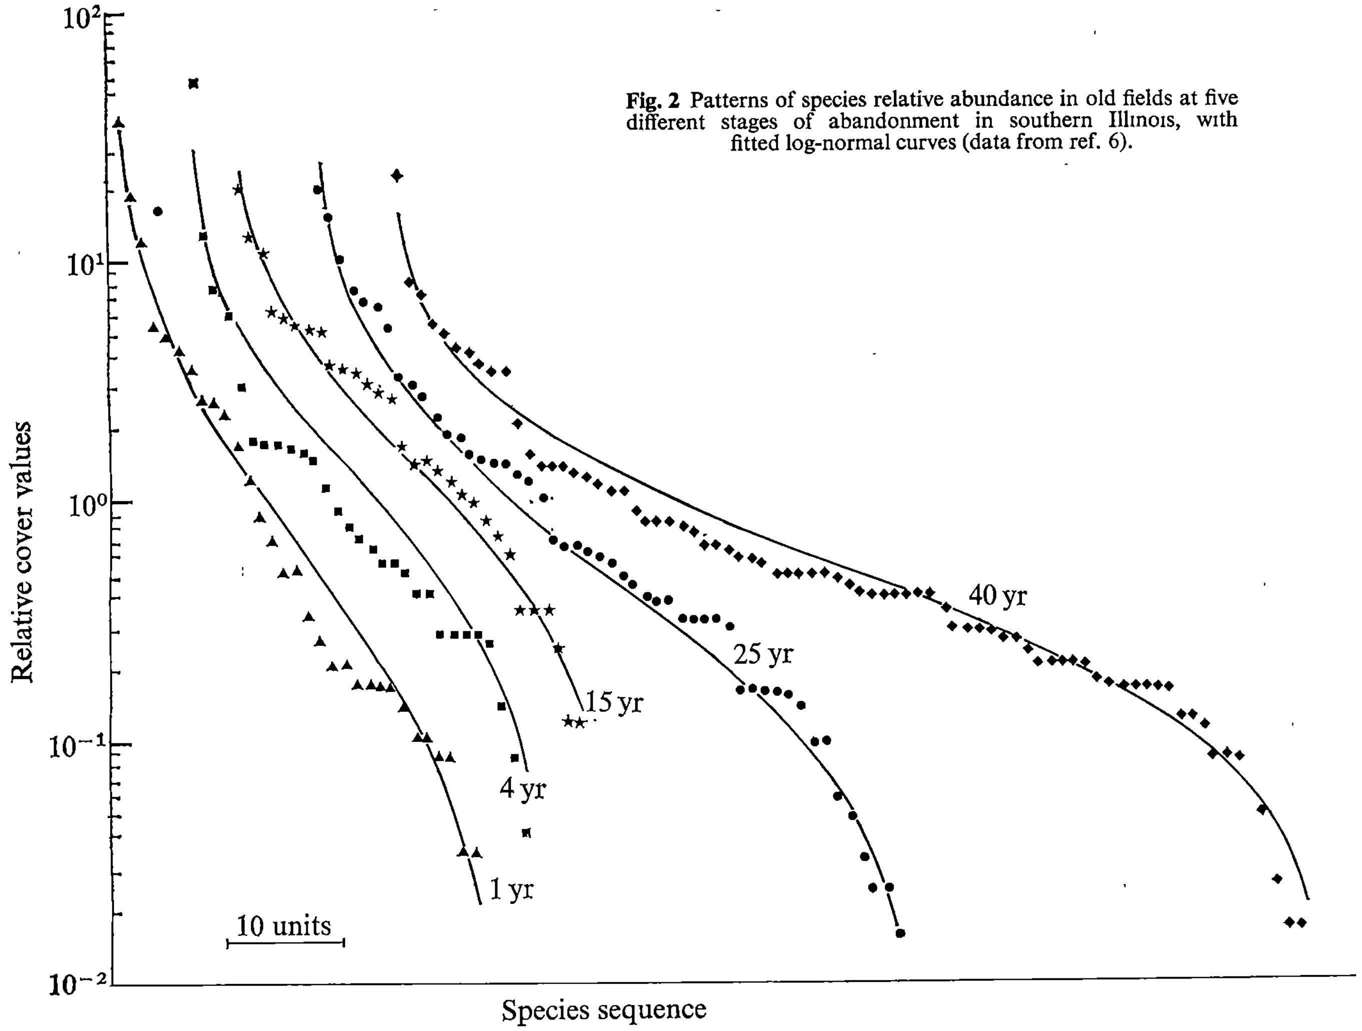

Fig. 2 Patterns of species relative abundance in old fields at five different stages of abandonment in southern Illinois, with fitted log-normal curves (data from ref. 6).

Table 2 Diatom samples showing replicate variability of the mid-range statistic Q evaluated directly from the data and from the parameters of the log-series and log-normal models (data from ref. 4)

	Replicate								Mean	Variance
	1	2	3	4	5	6	7	8		
Empirical Q	20.9	17.9	26.4	22.4	20.1	19.2	19.8	23.7	21.3	7.54
Log-series α	19.2	18.3	20.4	19.9	20.5	19.7	18.2	19.9	19.5	0.77
Log-normal cS^*/σ	21.9	20.7	24.3	21.4	23.8	22.7	21.2	23.1	22.4	1.67

estimated much more efficiently than by direct evaluation from the relative frequencies. The mid-range statistic Q is particularly simply represented in terms of the parameters of both the log-series and log-normal models; for the log-series $Q = \alpha$, Fisher *et al.*'s index of diversity[3], whereas for the log-normal $Q = cS^*/\sigma$, where S^* is the hypothetical number of species in the population, σ is the standard deviation of logged abundances, and c depends on the proportion of species present in the sample. When all species are present, $S^* = S$ and $Q = 0.371S/\sigma$. Fitting a model enables all the information in the data to be utilised in estimating Q, this should result in smaller variation between replicates. This is shown in Patrick's diatom samples[4] (Table 2) for which Q has been estimated directly from the data and from the parameters of the fitted log-series and log-normal models, for each of the eight replicates. The mean values of Q are similar for all three methods but the advantage of fitting a model is shown in the resulting smaller replicate variability; this will enable better discrimination between sites (Table 1). The choice of model is of secondary importance but the log-series parameter α shows somewhat smaller variability than the log-normal S^*/σ (Table 2), demonstrating the advantages of using the simpler model, even though the log-series is, for this series of data, nearly always a worse fit[5].

Table 3 Change of diversity with succession in abandoned fields in Southern Illinois (data from ref. 6)

Stage of succession (yr)	1	4	15	25	40
Information statistic, H	2.0	1.7	2.8	2.9	3.2
Mid-range statistic, Q	5.6	8.4	8.0	10.0	24.1
Number of species, S	31	29	30	50	77
Log-normal σ	1.9	1.5	1.3	1.7	1.4
$Q = 0.371S/\sigma$	6.2	7.1	8.4	10.7	20.6

The importance of choice of diversity statistic is also seen in data by Bazzaz[6] on the change of pattern with plant succession in old fields in Illinois (Fig. 2). In this instance, the pattern of ecological succession, as summarised by May[7], assumes that in the early stages of succession the Niche Pre-emption Model applies and the ranked abundances of the species may be expected to follow a geometric series. Later, a multiplicity of other factors affecting abundance come into play, and the distribution of species abundance moves closer to the log-normal form. Although this sequence of models may have theoretical appeal, on purely statistical grounds the use of two models seems unjustified, for the data seem to support just as well the use of the same, log-normal distributional model to fit each stage of succession (Fig. 2).

Bazzaz evaluates the information statistic, H, for fields at each stage of succession, and argues that after an initial drop, diversity increases rapidly from year 5 to 15 and then only slowly over the remaining years (Table 3). H seems to reflect the relative abundance of a small number of dominant species. The pattern suggested by the great majority of species is, however, very different, indicating a slow initial increase in diversity followed by more rapid increase in the later stages, changes reflected by the mid-range statistic Q. With one common distribution fitted to all the data we may use the parameters from the model to chart the increase in diversity, described, not by the number of species S, or evenness σ, taken individually but by their ratio S/σ (Table 3), which more closely reflects the visible trend.

Errata

In the article "Promotion and retardation of heat transfer by electric fields" by Y. Asakawa (*Nature*, **261**, 220; 1976) the last sentence to the legend to Fig. 2 should read . . . The cylinder was heated within an electric furnace, and cooling was 1.7 times faster (*b*) and 1.8 times slower (*c*) than in case *a*. and not as printed.

In the article "Age relationships along the Hermitage Bay–Dover Fault System, Newfoundland by J. Blenkinsop, P. F. Cucman and K. Bell (*Nature*, **262**, 377; 1976) the figure in the fourth line of the first paragraph should be 400 Myr and not 4 Myr as printed.

In the article by O. K. Wilby (*Nature*, **262**, 387; 1976) the title should read ". . . and the effects of antibiotics . . ." and not antibodies as printed.

Nature **Index and Binders**

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* fits into four binders).
Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

matters arising

Nuclear composition of cosmic rays

WHEN the phenomenological constant in the local source model of Rasmussen and Peters[1] is given a more physical basis, its large value cannot be easily understood.

I begin by deriving their equation (1). For each species i, the steady-state equation for the density η_i^b[cm^{-3} GeV^{-1}], of high energy particles coming from a background of uniformly distributed sources with strength S_i^b[cm^{-3} s^{-1} GeV^{-1}] and undergoing spallation is

$$\frac{d\eta_i^b}{dt} = 0 = -n\sigma_i c\eta_i^b + S_i^b + \sum_{j>i} n\omega_{ij} c\eta_j^b \qquad (1)$$

where n [cm^{-3}] is the mean density of hydrogen, c is the velocity of light, and the cross sections σ_i and ω_{ij} [cm^2] were defined by Rasmussen and Peters. To write equation (1) in terms of the total density, η_i, and total source strength, S_i, let L_i[s^{-1} GeV^{-1}] be the mean luminosity of the cosmic ray sources, then

$$\eta_i^b = \eta_i - \eta_i^l,\ S_i = NL_i/V_G \qquad (2)$$

$$S_i^b \sim (1-N^l/N)S_i \qquad (3)$$

$$\eta_i^l = \sum_\alpha \frac{L_i^\alpha f_\alpha}{4\pi c d_\alpha^2} = \left(\sum_\alpha \frac{L_i^\alpha f_\alpha}{4\pi c d_\alpha^2}\frac{V_G}{NL_i}\right)S_i = \frac{KS_i}{nc} \qquad (4)$$

where N is the total number of sources, V_G is the containment volume, L_i^α is the luminosity of and d_α the distance to the αth of the N^l local sources, and f_α is the enhancement from diffusion. Note that equation (4) pertains to stable nuclei and assumes negligible spallation. After substituting equations (2)–(4), equation (1) becomes

$$\frac{S_i}{n} = \frac{\sigma_i c\eta_i - \sum_{j>i} \omega_{ij}[c\eta_j - KS_j/n]}{1+\sigma_i K} \qquad (5)$$

(if $N^l/N \ll 1$). If $S_i/n \to S_i$ (the relative strength) and $\eta_i c \to F_i$, then equation (5) becomes equation (1) of Rasmussen and Peters.

Next, approximate the transport from a steady source by assuming isotropic, three-dimensional diffusion in an infinite medium (see ref. 2). Then the equilibrium value of the factor f_α is given by[3]

$$f_\alpha = (d_\alpha c/D) \qquad (6)$$

and, after an interval Δt, the root mean square distance, r_{rms}, for newly produced particles is

$$r_{rms} = (6D\Delta t)^{\frac{1}{2}} \qquad (7)$$

where $D(\equiv\lambda c/3)$ is the diffusion constant and λ is the scattering mean free path. If spallation is negligible, the random path $c\Delta t$ must be much smaller than a spallation mean free path for the heaviest element injected by a source. Thus equation (7) implies that the boundary of the local source region, R^l, is

$$R^l = (2\lambda\xi/n\sigma_U)^{\frac{1}{2}} = 180(\lambda/n)^{\frac{1}{2}}\text{ pc} \qquad (8)$$

where $\xi = 0.1$ permits up to 10% spallation, $\sigma_U(=2\text{ barn})$ is the spallation cross section for uranium, and where the units for λ and n are pc and cm^{-3}. Also, if all of the sources are distributed uniformly, the mean number of local sources is just

$$\langle N^l\rangle = \left(\frac{4}{3}\frac{\pi(R^l)^3}{V_G}\right)N \qquad (9)$$
$$= 7.2\times10^{-5}(\lambda/n)^{3/2}N$$

for $V_G = 10^{67}$ cm^3.

Rasmussen and Peters then found the source abundances of Li, Be, and B were minimised if $K = 0.02$ mbarn^{-1}. From equations (4), (6), and (9) this means

$$d_* = 0.90(N^l/\langle N^l\rangle)(\lambda/n)^{\frac{1}{2}}\text{ pc} \qquad (10)$$

where d_* is the equivalent distance to the local sources defined by

$$\frac{1}{4\pi d_*} = \frac{1}{N^l}\sum \frac{L_i^\alpha/L_i}{4\pi d_\alpha} \qquad (11)$$

Note that if the local sources were identical and spherically distributed, then equation (11) says $d_* = (2/3)R^l(L_i/L_i^\alpha)$. While if there is only one local source $d_* = d_\alpha(L_i/L_i^\alpha)$.

Equation (10) poses a severe problem for the local source model. If $N^l \approx \langle N^l\rangle$, $d_* \sim 1$ pc, which implies either the source(s) is extremely close or extremely luminous. If $N^l \sim 30\langle N^l\rangle$, then d_* becomes acceptable, but the total number of sources becomes uncomfortably small. Using equation (9), such a fluctuation yields 2,300 sources (5 local) but with a probability of 9.2×10^{-7} (according to Poisson statistics). These problems become even more severe if the enhancement factor, f_α is set to unity.

To summarise, the size of the phenomenological constant K seems inconsistent with a physical interpretation in terms of source properties and distances. The difficulties in understanding the small value of d_* arise because the model requires the local source(s) to contribute extremely large amounts of unspalled C and O to match the observed L/M ratio.

I thank C. McKee and R. Gordon for discussions. This work was supported by NASA.

The cosmic X-ray background

MATTER–antimatter annihilation has had great appeal in astrophysical situations involving apparently overdrawn energy budgets. In spite of observational evidence that antimatter is no panacea[1], annihilation theories rise periodically, phoenix-like, in explanation of a wide class of astrophysical phenomena. In a recent letter, Carlqvist and Laurent[2] proposed that the X-ray background (1–100 keV) arises from Compton scattering of starlight photons by annihilation-produced, relativistic electrons and positrons. We show here that the Carlqvist–Laurent proposal is in conflict with γ-ray and neutrino observations. Were the X-ray background caused by annihilation produced electrons, the 100-MeV γ-ray flux would exceed that observed[3] by six to ten orders of magnitude, the muon-neutrino flux would exceed the observational upper limit[4] by one to five orders of magnitude and, a flux of 511 keV annihilation γ rays would be produced in excess of that observed[5] by up to eight orders of magnitude.

To produce the cosmic X-ray background, Carlqvist and Laurent[2] require the Universe to be filled with annihilation-produced electrons and positrons at a density $n_e \simeq 10^{-9}$ cm^{-3}. Since, in a typical annihilation, roughly one γ ray ($\sim$100 MeV) is produced for each electron[1], the γ-ray flux at Earth should be

$$F_\gamma \simeq cn_\gamma \simeq cn_e \simeq 30\,\mathrm{cm^{-2}\,s^{-1}} \tag{1}$$

This predicted flux exceeds that observed[3] by some six orders of magnitude. To avoid this embarrassment, Carlqvist and Laurent[2] suggest that the γ rays may be absorbed if annihilation were to occur in galactic nuclei instead of intergalactic space. Since the range of a 100-MeV photon exceeds the range of a 100-MeV electron (because of annihilation, the range of a 100-MeV positron is even shorter), it is impossible to absorb the γ rays without, first, stopping the electrons. Furthermore, since the electrons are tied to magnetic fields[2], they must pass through more material than the γ rays to escape from the annihilation volume. There is no way to bury the γ rays without also interring the electrons and positrons.

Although the previous discussion shows that the density of annihilation-produced electrons must be at least six orders of magnitude lower than that required by Carlqvist and Laurent[2] to produce the X-ray background, it is of interest to consider two other, independent constraints which support this conclusion.

As Steigman and Strittmatter[6] have shown, a typical annihilation yields two detectable μ neutrinos for every three electrons. Such annihilation-produced neutrinos are extremely difficult to detect and have been of only marginal value in constraining matter–antimatter theories[6]. The Carlqvist–Laurent proposal[2] is virtually unique in predicting a flux of μ neutrinos which exceed the upper limit to the observed flux[4] (F_{ν_μ} (obs) $\lesssim 3$ cm^{-2} s^{-1}).

$$F_{\nu_\mu} \sim cn_{\nu_\mu} \simeq 2/3\, cn_e \simeq 20\,\mathrm{cm^{-2}\,s^{-1}} \tag{2}$$

The neutrinos, of course, will not be absorbed in the annihilation region.

Finally, a relativistic positron in a medium of density n will annihilate in a time $t \simeq 10^{14}\ n^{-1}$ s, producing two 511-keV γ rays. The predicted flux of these annihilation γ rays is

$$F_{511} \simeq 10^5 n\ \mathrm{cm^{-2}\,s^{-1}} \tag{3}$$

For an average intergalactic density[7] ($n \simeq 10^{-7}$ cm^{-3}), the predicted flux exceeds that observed[5] (F_{511} (obs) $\lesssim 2\times10^{-3}$ cm^{-2} s^{-1}). In the Carlqvist–Laurent scheme[2], the situation is much worse, however. They require the annihilation to occur in quasars or galactic nuclei where the ambient density is very high. For example, for an average galactic density ($n \simeq 1$ cm^{-3}), the 511-keV flux would exceed that observed[5] by some eight orders of magnitude. Furthermore, every electron or positron which annihilates to produce a 511-keV γ ray was originally produced along with γ rays and neutrinos. Thus, the γ-ray flux would exceed that observed by some ten orders of magnitude and the μ-neutrino flux would exceed the observational upper limit by some five orders of magnitude! (The reason for the increase over our earlier estimates is that Carlqvist and Laurent[2] assumed that the electrons and positrons lived for $\sim 10^{10}$ yr; however, because of annihilation, their lifetimes are much shorter and, thus the original annihilation rate must be increased by the ratio of the age of the Universe to the lifetime of the electrons.)

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

It is clear that observational limits to the flux of annihilation products (γ rays and neutrinos) provide serious constraints to annihilation as an astrophysical energy source[1,6]. Since the recently proposed[2] annihilation explanation of the X-ray background is incompatible with these limits by many orders of magnitude, it is untenable.

CARLQVIST AND LAURENT REPLY—In Steigman's[1] criticism of our paper[2] he raises three points, with which we shall deal in order. One of these points concerns the γ rays produced by collisions of annihilation electrons (positrons) with positrons (electrons) in intergalactic space. Steigman believes that two 511-keV γ rays are formed in each electron–positron annihilation. This is not correct. If one highly relativistic electron (positron) annihilates on a positron (electron) at rest, one very high energy photon is produced and one photon with an energy in the region $m_ec^2/2$ to $\sim m_ec^2$. Consequently no discrete γ line is formed but a continuous spectrum. Steigman further uses a value of 10^{-7} cm^{-3} as the average intergalactic particle density, which is rather the density of smeared out galactic material. The true intergalactic density is not known. It should be pointed out that there is no reason why electrons and positrons must penetrate galaxies, which may be shielded by their magnetic fields.

A second point that Steigman raises concerns the production of γ rays in connection with the proton–antiproton annihilation. His objection here is based on a homogeneous model and does not apply to the model used by us. If annihilation occurs as a result of collisions between matter and antimatter objects which are sufficiently dense, most of the γ rays from the annihilation will be absorbed by the objects themselves[3,4]. The annihilation electrons and positrons may, on the other hand, be temporarily confined by magnetic fields to regions with a much lower density than in the surroundings and then be released into intergalactic space. One cannot therefore state categorically, as Steigman does, that the γ rays cannot be absorbed without stopping the electrons and positrons.

Steigman's third point concerns μ neutrinos formed on annihilation. He has used our suggestion to estimate the flux, and finds that it exceeds the measured number by one order of magnitude. It should be stressed that this estimate is necessarily very uncertain for two reasons. First, we have calculated the electron density only to an order of magnitude; and secondly, it is questionable how much value one should attribute to the old experiments referred to.

Finally it should be pointed out that Steigman has implicitly assumed an homogeneous cosmological model. If, however, the metagalactic model[5-7] is adopted, neutrinos and γ rays created long ago would have escaped through the boundary of the system.

In itself it is legitimate to use specific models but Steigman uses specific models in an illegitimate way to draw general conclusions.

reviews

Games of chance and necessity

I. Prigogine

Das Spiel: Naturgesetze Steuern den Zufall. By Manfred Eigen and Ruthild Winkler. Pp. 404. (R. Piper: Munchen and Zurich, 1975.) DM38.

TODAY, we are very far from the ideals of classical science centred on stability and permanence. We now see that such qualifications apply only to very limited aspects. Wherever we look, we discover evolutionary trends leading to diversification and increasing complexity. The monograph by Eigen and Winkler provides us with an excellent introduction to this new, more dynamic, vision of the physical world.

Dr Eigen is one of the key figures in contemporary physical chemistry and molecular biology, but the present work goes far beyond the field to which Eigen has made important contributions. It spans an extraordinarily wide range from fundamental concepts in mathematics and theoretical physics such as game theory or symmetry, to problems of aesthetics and epistemology. It shows that a synthetic approach to both the scientific and cultural problems of our time is still possible.

Photo: R. Piper & Co. Verlag

Ruthild Winkler and Manfred Eigen

The central theme is self-organisation. How can complexity arise spontaneously? The approach taken by the authors is clearly indicated in their Preface: ". . . All happenings in our world are similar to a big game in which only the rules are fixed *a priori* . . . We consider the game to be the natural phenomenon which, with its dichotomy of chance and necessity, is the basis of all change" (translation by the reviewer). This starting point leads to the search for unity in nature "as revealed by relationships between structures" and for unity between nature and spirit "as revealed by the existence of languages both in molecular biology and in human communication". The central theme, Nature as a game, is analysed using many examples.

It is impossible to analyse in detail the content of this monograph, which is subdivided into four parts, covering the simplest situations which game theory and physics can analyse, and ranging to problems of ecology, linguistics and aesthetics (the chapter on music is specially informative and original).

The concept of game (or play) is taken as the basis of both the unity and the self-organisation of the physical world. This theme is a recurrent one in the German *Natur Philosophie* of the romantic period (*Histoire de la Philosophie,* **III**, Encyclopedie de la pléiade, Gallimard, 1974). According to this view, game (or play) is the very expression of the creativity of Nature. It is interesting to note the contrast between the intellectual atmosphere of Eigen and Winkler's book with that of Monod's classic *Chance and Necessity* (Editions du Seuil, 1970). Monod stresses the analogy between living beings and chemical machines, and this analogy is repeated several times. Monod is, in fact, following in this respect the mechanistic cartesian tradition so strong in French thought. It is not surprising that, starting from this view, he has great difficulties in incorporating adaptation and biological evolution in his theory. Life appears as a phenomenon existing *de facto* but not *de jure,* as its presence can only be understood in terms of extremely unlikely, even unique, events.

Eigen and Winkler avoid, from the beginning, such difficulties as games having both deterministic and stochastic aspects: the rules are given in a deterministic fashion, whereas the time sequence of events contains stochastic elements. Instead of opposing chance and necessity, Eigen and Winkler show how these two aspects may cooperate to produce the complexity and diversity we observe in Nature.

Obviously, in a book devoted to a synthetic view of Nature the problems are of such a wide range and depth that different opinions may be held. This is only one more positive aspect which must be credited to the authors.

For example, it is difficult to accept the postulate of Eigen and Winkler that long time processes may all be identified with games. Games are mathematically associated with semigroups, such as those involved in Markov processes. On the other hand, classical and quantum mechanics lead to dynamic groups, involving unitary transformation. The transition from dynamic groups to games contains all the difficulties of going from dynamics to the theory of probabilities. There is no reason to believe that the description of the motion of a harmonic oscillator will ever need new elements over and above those contained in dynamics. Inversely, there is no reason to believe that probabilistic laws such as those describing Mendel's laws will ever be reduced to deterministic schemes. We now begin to understand that a minimum amount of complexity will lead to the introduction of stochastic elements where long time scales are involved (J. Moser, *Stable and Random Motions in Dynamical Systems*, Princeton University Press, Princeton, 1974). It seems that no reduction of Nature to a single fundamental level (either law or game) is possible. We have to accept a more complex situation involving the continued interplay between multiple levels (such as the interplay between macroscopic and microscopic levels emphasised by Bohr and Rosenfeld).

Also, the distinction between rules and events as used by Eigen and Winkler seems to be somewhat too rigid. In particular, when dealing with problems involving human behaviour, we cannot really speak of *given* rules. The games are so highly non-linear that essentially the rules themselves become situation-dependent. A well-known example is that of traffic flow, in which the strategy of the drivers depends on the specific situation (I. Prigogine and R. Herman, *Kinetic Theory of Vehicular Traffic*, American Elsevier, New York, 1971).

An important feature of the book by Eigen and Winkler comes from the fact that it shows how to go beyond the classic paradigms of molecular biology. Molecular biology has essentially been aiming to identify and isolate the characteristic biomolecules. Because of the very success of molecular biology it becomes today possible to proceed in new directions, and to relate structure on the supermolecular level to the characteristic properties and interactions of these biomolecules. To do so we need as emphasised by Eigen and Winkler, both conservative and dissipative structures. Conservative structures arise mainly through short range interactions (valency and van der Waals' forces), whereas dissipative structures result from chemical kinetics and transport processes if suitable conditions are satisfied. An essential feature of dissipative structure is that they depend on the system as a whole, or alternatively that they are similar to long range forces that lead to coherent behaviour.

Interesting chapters are devoted to the laws of population dynamics and to Darwinian evolution theory. Again, many points deserve a more detailed discussion. Can Darwinian theory really reduce to a model of molecular kinetics involving competition, similar to that operating for macromolecules? It seems to me that the position of Eigen and Winkler is somewhat optimistic, since the molecular mechanism of genetic fluctuations on one side and the laws of ecology on the other are still far from being clarified.

Still, it is interesting to apply models to specific situations, as in Eigen's original work, to be able to attach a precise meaning to concepts such as the survival of the fittest.

There is a deep concern with human fate. To quote Eigen and Winkler: "Man is neither a mistake of Nature nor is Nature taking care automatically of his preservation. Mankind is participating in a big game the result of which is still open. Man has to develop his potentialities to assert his role as a player in order not to be reduced to a mere object of chance" (translation by the reviewer). ☐

Professor Prigogine is Professor of Physics at the Free University of Brussels, Belgium.

Lay guide to mircobiology

Invisible Allies: Microbes and Man's Future. By Bernard Dixon. Pp. 251. (Temple Smith: London, May 1976.) £4

IT was difficult for me, now approaching the end of a career in microbiology, to judge a book intended for lay-people. Too often 'nit picking' intervened. The opinion which follows is partly my own and partly that of friends and relations, all lay-people (except for an acquaintance with me). The title of the book underlies an admirable intention. That is, it seeks to dispel the attitude, still too common even in our new students, that sees microbiology in terms of medicine and thus all microbes as enemies. How disappointing, for instance, was the BBC Television series *Microbes and Man* in this respect: Dixon's book might well form the basis of a remedial programme. The treatment has less detailed biology than that out of the classic *Microbes by the Million* and is possibly less professional than John Postgate's *Microbes and Man* (obligatory for our first-year students). Dixon's book should be obligatory to all lay people with a spark of interest in their own relationship to the living world. After a brief, rather sketchy description of microbes, it goes on to describe their role in the biological production cycle, and their exploitation. Besides having value in their own right microbes now play an important role in experimental biology; this, and especially the advances in molecular biology, are well treated but some of the examples used in talking about evolution could have been more relevant. Microbial infection, so often seen as an all-or-none process, is placed in the perspective of ecology. Aspects of microbiology now causing alarm such as germ warfare and genetic engineering are briefly discussed. A general criticism was of the rather concentrated writing and the lack of good diagrams or other illustrations. These undoubtedly would have improved the book considerably and reduced the concentrated wordiness, provided time for reflective pauses and given some indication of the scale of industrial process.

If a good book is one that helps a change of mind then this is undoubtedly a good book. My copy will be to hand to press on those who wonder how I have spent my time and their taxes. **D. E. Hughes**

D. E. Hughes is Professor of Microbiology at University College, Cardiff, UK.

Ultrastructural masterpiece

Ultrastructure and The Biology of Plant Cells Pp.312 (49 plates). £27.50. *Plant Cell Biology: An Ultrastructural Approach.* Pp.280. £2.75 paper. By Brian E. S. Gunning and Martin W. Steer. (Arnold: London, 1975.)

THERE is currently available a number of books dealing with the ultrastructure of plant cells, each of which provide a series of excellent electron micrographs. They are, however, often flawed by an indifferent text. The pair of books presented here are a welcome exception. The smaller student book is derived from the other (a reference tome), and they collectively represent a masterpiece. The authors have been wholly successful in the enormously difficult task of illustrating the dynamic nature of cell structure using the essentially static medium of electron microscope snapshots.

The major book, although hideously expensive, is beautifully produced; and the photographs, collected together at the end, are superb. There are 49 plates, almost all of which comprise multiple montages; and virtually every conceivable aspect of plant cell structure, from general features common to all cells, to specialised structures, such as cuticles, pollen grains and glands are represented The illustrated material is amply supported by an extensive and erudite text which deals with the subject at a very high level—not really suitable for students—but of great value to university teachers and research workers.

The book begins, as is almost obligatory with this topic, by describing in detail the various methods used to prepare, section and visualise plant material, giving due emphasis to the advantages and shortcomings of all the techniques. After a general chapter on cell structure with particular reference to membranes, the coverage subsequently works from the outside inwards—that is, cell wall and plasma membrane, vacuole and tonoplast, nucleus, endoplasmic reticulum, Golgi apparatus, mitochondria, plastids, microbodies and sphaerosomes, microtubules and microfilaments, and cell division. As may be expected from these authors, the chapter on plastids is particularly rewarding, with a masterly coverage of the structure of the granum and the prolamellar body. This chapter, however, is merely a prominent peak in a high mountain range. I was particularly impressed by the careful attention of the authors to comparative sizes of cell constituents. The book is finished off with a scholarly treatment of the cell as an integrated unit and a very comprehensive list of references.

The smaller book is in reality a reprint of the 49 plates of the larger book together with the figure legends and a minimum of extra text. As a book for students it is likely to be quite useful, although it could have been improved by the addition of a précis of the text from the larger book. It seems rather remarkable that the figures of the larger book can be put on sale for one-tenth of the price of the whole book, when we are always being told that half-tone reproduction is extremely expensive. Publishing houses clearly move in a mysterious way . . .

Apart from the price, the larger book is an excellent buy and lecturers might well consider using it as a basic text, recommending their students to use the cheaper version with the photographs. **Harry Smith**

Harry Smith is Professor of Plant Physiology in the Department of Physiology and Environmental Studies at the University of Nottingham, UK.

Optical multilayers

Optics of Thin Films. (An Optical Multilayer Theory.) By Zdenek Knittel. (Wiley Series in Pure and Applied Optics.) Pp. 548. (Wiley-Interscience: London and New York, February 1976.) £15; $33.

THE appearance of this volume is timely. Since the appearance of the first book on this subject, in 1955, considerable developments have occurred, and the optical multilayer has become a normal—and in some cases crucial—component in many optical systems. With the availability of computers, multilayer calculations have become straight-forward and great progress has been made in automatic design routines in which the computer is given the desired reflection–transmission curve and is asked to determine appropriate layer thicknesses. Dr Knittl's long experience in the optical industry has put him in a strong position to write with authority on the many developments of the past twenty years. Many of the methods described enable an insight to be obtained on the way in which multilayer properties are influenced by changes in particular layers. Such methods can assist in design problems without the need for mammoth number-crunching powers and can serve for many simple systems. A useful section is included on inhomogeneous layers which still remain to be fully exploited in the practical field.

The book will form a useful reference work for the multilayer designer. There are one or two unfortunate features which make for difficulties in reading. In the text, the boundaries between layers are envisaged as being in a vertical plane, so that waves are described as going towards right or left, whereas in figures the boundaries are shown as horizontal planes. Some graphs have no labels on the axes and in some cases too little information is given to understand readily the significance of graphs bearing several curves In one example, curves are given for an anti-reflecting system embedded in a medium of refractive index 1 2—a curious choice in view of the absence of any real material with this value of refractive index. These are, however, fairly minor points.

O. S. Heavens

O. S. Heavens is Professor of Physics at the University of York, UK.

SCIENCE EDITOR

THE MACMILLAN PRESS

As our rapid but controlled growth continues, we have decided to separate the pure science and medical lists. We are therefore seeking someone to take over and develop our established pure sciences programme.

The successful applicant will report to the Publisher for the Scientific, Technical & Medical Division, but will assume complete responsibility for both the undergraduate and postgraduate programmes in chemistry, physics, biochemistry, biological sciences, computer science, and applied mathematics.

Ability, enthusiasm, and potential are more important than either age or experience, although we will be looking for some publishing background.

The appointment is based in Basingstoke. The salary will be competitive and a company car will be provided. Applications (which will be treated in strictest confidence) to:

Sydney A Josephs
Publishing Director
The Macmillan Press
Houndmills
Basingstoke
Hampshire RG21 2XS

obituary

Harry Nyquist, widely known for his theoretical studies and practical inventions in the field of communications, died on April 4 at the age of 87 in Harlingen, Texas. Born in Nilsby, Sweden, on February 7, 1889, Nyquist was the son of Lars and Katarina Nykvist. He emigrated to Minnesota in 1907 and taught at the Southern Minnesota Normal School in Austin, Minnesota. Nyquist earned his BA, BS and MS degrees from the University of North Dakota, and in the summers worked at the National Bureau of Standards and the US Patent Office.

He joined the American Telephone and Telegraph Company in 1917, shortly after he had obtained his PhD in physics from Yale University, and moved to the Bell Telephone Laboratories in 1934.

From 1917 to 1921 he worked primarily on the development of the metallic telegraph system and methods of measuring telegraph distortion. From 1921 to 1935 he devoted considerable time investigating television techniques, and worked on projects aimed at extending and improving long-distance telephone circuits.

After 1935, Nyquist devoted most of his time to research work where he applied his broad knowledge and analytical ability to the most difficult of challenges in the field of communications development. For the two years before his retirement in 1954 he was Bell Laboratories' Assistant Director of Systems Studies.

Nyquist was awarded 138 patents during his 37 years with the Bell System. Many of his inventions and theories are widely accepted as fundamental to voice, picture and data transmission. His discovery of the conditions necessary to keep feedback circuits stable, the 'Nyquist Criterion', brought him widespread acclaim. It is used not only in the study of electronic devices, such as amplifiers, but even in the study of human regulating processes—for example, to describe the way in which a person steers a car.

He gave the first quantitative explanation of thermal noise, and through theoretical analysis determined the minimum band of frequencies required to transmit various kinds of communication signals. These studies laid the foundation for modern information theory and data transmission. In the television field, Nyquist invented a method of transmission used in broadcasting today, and also discovered a way to correct delay distortion of TV images.

Among the many honours Nyquist received were: the Mervin J. Kelly Award of the AIEE (1961), the National Academy of Engineering founders Medal (1969) and the Rufus Oldenburger Medal from the ASME (1975).

Harald Trap Friis, a pioneer in the development of radio communications and an initiator of microwave radio transmission and radio astronomy, died on June 15. He was 83 years old.

Friis was born in Naestved, Denmark, February 22, 1893. He attended the Royal Technical College in Copenhagen, where he received his Electrical Engineering degree in 1916 and his Doctorate in Science in 1938. From 1917 to 1918 he worked as Technical Advisor at the Royal Gun Factory in Copenhagen. In 1919, upon receipt of a Fellowship from the American-Scandinavian Foundation, he moved to the United States to study at Columbia University.

In 1920 Friis joined the Western Electric Company's research department, the predecessor organisation to Bell Laboratories, and in the twenties he designed the first commercial 'double-detection super-heterodyne broadcast radio receiver', the forerunner of present-day radios. In 1923, Friis spent several months in England devising receivers for a long-wave transatlantic telephone link. In the decade that followed he is credited with designing a receiver that automatically compensated for fading signals, an improved directional antenna, and methods for recording static and measuring fading shortwave signals.

His most famous achievement was, however, in the design of antennae. One designed by Friis together with Bell Labs colleague, Karl Jansky, was the first to detect 'star noise' in 1932—the birth of radio astronomy. The rhombic antenna designed by Friis and another colleague, Edmond Bruce, found worldwide use in shortwave radio telephony, and yet another of his antennae—the Multiple Unit Steerable Antenna—made it possible, Friis said, "to unravel the phenomena of shortwave transmissions". He was the coauthor of the book *Antennas: Theory and Practice* (1952).

In 1938 Friis moved from shortwaves to microwaves and created the horn-reflector antenna, now seen on tower tops all over the country. During this period Friis put together the basic elements of a microwave telephone system. A year after the end of the war, the first experimental microwave circuits based on Friis' designs were installed for domestic use and today, Bell System microwave radio facilities provide some 380 million miles of long distance telephone circuits.

Following his retirement, Friis spent 10 years as a research consultant to the Hewlett–Packard company in Palo Alto, California. He published an autobiography, *Seventy Five Years in an Exciting World* in 1971.
